Using only first and second moment information of the underlying probability distributions, we develop bounds on system performance to address issues related to the potential value generated due to risk pooling effects, the sensitivity of the demand correlations, as well as supplier and yield volatilities.

2 - Distributed Manufacturing System Design

Paula Penagos, University of Missouri - St. Louis, St. Louis, MO, United States, Haitao Li

With the rapid growth of advanced manufacturing and the prevalent use of Internet of Things (IoT), distributed manufacturing systems have been gaining traction in various industries as a new operational paradigm. Unlike the traditional centralized manufacturing system focusing on achieving economies of scale, a distributed system consist of decentralized facilities across regions that both compete for limited resources and collaborate to achieve some system-wide performance metrics.

We introduce a novel modeling framework for Production Planning in Distributed Manufacturing (PPDM), where a parent firm oversees resource allocation and transportation among multiple autonomous manufacturing facilities. Each facility independently optimizes its production to achieve their own (and conflicting) objectives such as profit maximization, market share, or carbon emission reduction. Transportation serves a dual role: resource distribution and customer demand fulfillment in the PPDM.

The model incorporates a *coopetitive* mechanism that blends both cooperation and competition. Facilities operate with asymmetric information, while the parent firm coordinates supply allocation to optimize global performance goals. A game-theoretic procedure is developed to support decentralized decision-making and system-wide optimization.

A numerical example illustrates trade-offs between production efficiency, transportation cost, and customer satisfaction. The results highlight the value of coordination in distributed systems. This framework bridges gaps between production planning, distributed manufacturing, and supply chain coordination by offering a data-driven, decision-support approach. It provides a vehicle for designing agile, resilient, and efficient distributed manufacturing systems with the *coopetitive* feature.

Keywords: distributed manufacturing, production and transportation planning, supply chain coordination, coopetition, game theory, math programming

3 - A GS1 Standard-Based Integrated Information System for EV Battery Manufacturing and Logistics

Seokho Yoon, Ulsan National Institute of Science and Technology (UNIST), Ulsan, Korea, Republic of, Yuseon Yun, Jaesung Kim, Yujin Song, Nayoung Lee, Namgyo Kim, Sang Jin Kweon

As the demand for electric vehicles (EVs) accelerates, ensuring transparency, traceability, and sustainability throughout the EV battery lifecycle has become a critical challenge. This study addresses this issue by developing an integrated information system based on GS1 standards to support standardized identification and traceability across the EV battery manufacturing and logistics process. The goal is to establish a data-driven framework that enables end-to-end lifecycle tracking from raw material input to final product packaging by assigning and managing GS1 codes at each critical stage of battery production, including electrode fabrication, assembly, activation, and packing. To this end, we design a GS1 code system tailored to key components such as binders, electrolytes, separators, and other materials, in order to enable comprehensive data aggregation and interoperability across manufacturers and suppliers. We then implement and test a prototype platform using sample process data collected from a domestic EV battery production line and validate its effectiveness in improving traceability and operational efficiency.

4 - Behavioral Implications of Costly Information Acquisition in Newsvendor Model: An Experimental Study

Jiayi Lin, Renmin University of China, Beijing, China, People's Republic of, Wanshan Zhu, Jinxing Xie, Xiaobo Zhao

In the era of information abundance, decision-makers navigate diverse channels for acquiring information, each with varying costs. Our study investigates how these costs influence the decision-makers to choose the accuracy of demand signal and to subsequently make order quantity decisions. The accuracy of demand signal is defined as the probability that the demand signal matches the actual demand realization value. In a newsvendor setting, we characterize the optimal accuracy of demand signal and the optimal ordering strategies as a function of the observed demand signal. Using these results as a benchmark, we conduct laboratory experiments to investigate human biases in information acquisition and inventory decisions. The experimental results show that decision-makers perceive information acquisition costs through Shannon information entropy rather than a linear function of information accuracy. Furthermore, we find that subjects are pulled towards the demand signals in inventory decisions, even when the accuracy of demand signal is zero. Based on these findings, we propose a behavioral model that considers Shannon information entropy and mental accounting. The simulations based on this behavioral model match well with the experiment. These results shed light on how human decision-makers acquire and use demand signal information for inventory decisions.

5 - Optimal Inventory Policy Under Information Sharing About Downstream Inventory Position

Byeongkwon Lee, Seoul National University, Seoul, Korea, Republic of, JeongWook Lim, Kun Soo Park

We investigate periodic review inventory management problems for a manufacturer in a decentralized supply chain under information sharing. The manufacturer orders from its upstream supplier and fulfills demand ordered by its downstream retailer. The upstream supplier has infinite capacity, provides a constant order lead time, and charges zero fixed ordering cost to the manufacturer. The downstream retailer faces independent and identically distributed customer demand, orders from the manufacturer according to a given (s, S) policy, and shares both the realized customer demand and its own inventory position with the manufacturer. The manufacturer incurs linear inventory holding and backorder penalty costs applied to overage and underage scenarios, respectively, and aims to minimize the long-run average holding and penalty costs. We propose an exact optimization algorithm to derive the optimal state-dependent base-stock policy. Furthermore, through comparative analysis with the case without information sharing, we provide insights into the value of information.

6 - Learning-Based Branch-and-Price-and-Cut Algorithm for the Scheduling Problem in the Steel Industry

Ying Meng, Northeastern University, Shenyang, China, People's Republic of, Shikui Wang

In this study, we address a cold rolling mill scheduling problem faced by a steel enterprise in China. The problem focuses on developing an optimal schedule by selecting and sequencing coils to meet the demands of the downstream mills. It is an extension of a classical vehicle routing problem with capacity and color constraints, and the objective aims to minimize the total penalty costs between consecutive coils and the setup costs. To solve the problem, we first formulate it into an arc-flow model and a set packing model. Then, we propose two valid inequalities to tighten the lower bound of the set packing model. A label setting algorithm with dominance rule and fathoming rule is designed to solve the pricing sub-problems. Additionally, to accelerate the process of column generation, we propose two properties to reduce the number of sub-problems that need to be solved. Finally, a machine learning-based branching rule is proposed to obtain the optimal solution for the problem. We validated the proposed algorithm's performance on randomly generated instances based on actual production data. The proposed algorithm outperforms the commercial solver CPLEX and can obtain optimal solutions for up to 72 coils with the learning-based branching rule.

7 - A Column Generation Based Algorithm to Steel Coil Assortment Optimization Problem

Yang Yang, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, Shenyang, China, People's Republic of, Lixin Tang

Steel companies usually produce a variety of steel coils to satisfy demand for a large number of sheeted products required by equipment manufacturers. The conflict between the batch production requirements and the various customer demands has made it inevitable to determine the best assortment of coil type and the assignment of these coil types to finished products so as to reduce production and inventory costs while satisfying as many needs as possible. To describe the problem, a mathematical model is formulated in which the expected inventory holding costs is estimated based on risk pooling economies. Then a column generation based algorithm is developed to solve the problem. Finally, the performance of proposed methods is tested based on randomly generated problem instances.

1 - Addressing Endogeneity in Healthcare Operations Through Copula-Based and Machine Learning Methods

Meera Simon, Indian Institute of Management Kozhikode, Kozhikode, India, Shovan Chowdhury

Measuring cost at the patient level is important for the measurement and improvement of value. Healthcare providers must therefore be able to provide coordinated care with minimal expenditure which requires accurate estimation of cost. Understanding the importance of individual-level factors that determine expenditure, researchers have developed models that consider several customer-centric factors like socioeconomic and psychological factors and used regression models to analyse the effect of customer profiles and other factors on expenditure. It is, however, established that endogeneity is an important problem that arises while using regression, and many impactful academic journals require that the issue of endogeneity be addressed. Though till 2015, the issue of endogeneity was not of immense importance in operations management, the note from the editors of the Journal of Operations Management published in 2018 emphasised the importance of addressing the endogeneity, encouraging models that could incorporate endogeneity. In our study, we identify two endogenous variables that commonly occur in healthcare (namely, Length of Stay (LOS) and total expenditure) and develop a model that can address endogeneity through bivariate copula which is an instrument-free approach that can effectively be used to model variables with suspected endogeneity. To accommodate other variables that are linked directly to the variables under study, we also use machine learning techniques.

2 - Advancing Kidney Transplant Outcomes Through Multi-Agent Exchange Optimization with Hla Compatibility Constraints

Shayan Sharifi, Wayne State University, Detroit, MI, United States, Melike Yildirim

Kidney transplantation remains one of the most effective treatments for end-stage renal disease, yet the global shortage of compatible organs and rising waiting lists highlight the need for more efficient allocation systems. This study presents a novel optimization framework that enhances transplant opportunities through Multi-Agent Kidney Exchange Programs (MKEPs), with a strong emphasis on biological compatibility and fairness. We develop and compare three mathematical models: (1) a baseline KEP model maximizing transplant count under basic blood and PRA compatibility, (2) an enhanced model that integrates a minimum Human Leukocyte Antigen (HLA) score to improve transplant quality, and (3) a multi-agent model that pools donor-recipient pairs across agents (e.g., hospitals, regions), ensuring fairness while maximizing both quantity and quality of transplants. The multi-agent model demonstrates superior outcomes by significantly increasing the number of transplants (up to 125% improvement over baseline) while maintaining stringent HLA thresholds. Realistic simulations and sensitivity analyses reveal key trade-offs between transplant quality and quantity, providing robust insights for policy design in national and international kidney exchange systems. The results highlight the potential of integrated MKEPs to transform organ allocation policy by balancing fairness, efficiency, and long-term clinical outcomes.

3 - Optimal Chemotherapy Scheduling Under Parameter Uncertainty Using Cem Based Policy Learning

Md Samiul Haque Motayed, The University of Texas at Arlington, Arlington, TX, United States, Shuo Wang

Cancer chemotherapy treatment poses significant challenges due to tumor heterogeneity and the adverse effects associated with drug administration. This necessitates intelligent dosing strategies that can balance treatment efficacy with patient safety. In this study, we present a feedback control framework based on the Cross-Entropy

Method (CEM) for generating adaptive chemotherapy policies. Unlike traditional open-loop strategies such as Pontryagin's Maximum Principle (PMP) or global optimization methods like Quantum Particle Swarm Optimization (QPSO), the approach learns closed-loop policies that can respond in real time to variations in tumor dynamics and treatment response. We first demonstrate that a single CEM-trained policy, calibrated using nominal patient parameters, can achieve favorable outcomes under ideal conditions. However, its performance significantly degrades under spatial parameter uncertainties, particularly in tumor growth rate and drug sensitivity. To mitigate this limitation, we propose an ensemble policy learning strategy, where multiple CEM policies are trained on perturbed patient profiles. During treatment, an expert selection mechanism is used to enhance adaptability. Through extensive numerical simulations, we show that the ensemble approach outperforms single-policy counterparts by reducing treatment cost variability and maintaining stable tumor suppression across uncertain patient scenarios. Compared to PMP, our method offers comparable performance while providing the added benefits of feedback structure, computational efficiency, and ease of implementation. The proposed ensemble policy learning framework offers a promising direction for personalized and adaptive chemotherapy scheduling in uncertain biomedical environments.

4 - Mixed-Integer Programming Formulations for Appointment Scheduling in Tandem System

Tengfang Huang, Shanghai Jiao Tong University, Shanghai, China, People's Republic of, Taotao He, Guohua Wan

This work addresses the appointment scheduling problem in tandem (multistage) healthcare service systems, where each patient requires a sequence of services across multiple stages. Previous research has established elegant structural properties, such as submodularity and L-convexity, for the single-stage appointment scheduling problem, enabling efficient algorithms for minimizing expected underage and overage costs under general discrete processing time distributions. However, when extended to tandem systems, these properties no longer hold due to the inherent interdependencies between service stages, which significantly complicates both the theoretical analysis and practical solution approaches.

Despite the extensive study of this problem in the literature, the structural complexity of large-scale tandem systems has been largely overlooked, making scalable optimization a persistent challenge. Building on recent advances, we explore the problem's hidden structure and propose a novel mixed-integer programming (MIP) formulation that enables the efficient solution of large-scale tandem system appointment scheduling problems. Our formulation is directly compatible with state-of-the-art optimization solvers, and, by exploiting structural insights, it facilitates practical computation for real-world healthcare applications. Numerical experiments demonstrate the effectiveness of our approach. This work advances both the theory and practice of appointment scheduling in multistage healthcare systems, providing a new framework for optimizing patient flow and resource utilization at scale.

5 - Modeling Emergency Healthcare Strategies and Capacity Planning During Pandemics

Eyyub Kibis, Montclair State University, Montclair, NJ, United States

COVID-19 has infected millions of people globally and caused significant mortality, underscoring the urgent need for effective detection, reporting, and response strategies by national governments. However, when preventative measures are inadequately implemented or delayed, the outbreak can escalate rapidly, placing immense strain on healthcare systems. To address these challenges, this study develops a compartmental dynamic model to simulate the spread of COVID-19 within a community setting. The model captures the transmission dynamics of the disease and evaluates the impact of various emergency policy interventions. By incorporating real-world outbreak data, we validate the model's predictive capability and assess the effectiveness of potential control strategies. Our findings suggest that the timely deployment of makeshift hospitals can significantly reduce patient density in conventional healthcare facilities, enabling a more efficient allocation of limited medical resources. These temporary healthcare facilities offer a flexible and scalable approach to expanding hospital capacity during crisis periods. The proposed model serves as a practical decision-support tool for state and local governments, helping to plan and implement responsive strategies that mitigate the impact of the pandemic and improve public health outcomes.

1 - An Introduction to AI Alignment Challenges and Progress

Mohsen Bayati, Stanford University, Stanford, CA, United States

The performance of state-of-the-art AI is typically measured on limited benchmarks, a paradigm that often fails to capture true real-world deployment needs. This gap is rooted in the problem of model underspecification, where models learn shortcuts that lead to unexpected failures. This tutorial uses this concept as a starting point to introduce the field of AI alignment. Following a brief survey of recent techniques, it will focus on the post-hoc control of opaque models, discussing recent progress and the significant research challenges that remain.

1 - Prognostics and Diagnostics of Multi-Sensor Systems with Unknown and Unquantified Failure Modes via Bayesian Nonparametric Process Mixtures

Kani Fu, University of Florida, GAINESVILLE, FL, United States, Minhee Kim

To prevent unexpected failures in manufacturing systems, failure mode recognition and prognostics play a crucial role in prognostics and health management (PHM). However, existing methods often rely on strict assumptions, which limit their applicability. First, they typically assume that the number of failure modes is known, which makes it challenging to handle non-stationary and complex systems. Second, they presume that the failure modes of historical units are known, yet in practice, such information is often unavailable, particularly for new systems. Moreover, damaged units are frequently discarded without identifying their primary failure mechanisms. To overcome these limitations, we propose a Bayesian nonparametric framework, which combines the Dirichlet process mixture model (DPMM) and a neural network to simultaneously learn clusters of failure mode and a remaining useful life (RUL) prediction model. Specifically, our framework iteratively updates both the number of failure modes and the parameters of the RUL prediction model, enabling it to adaptively identify dominant failure mechanisms and improve prediction accuracy. Experiments on aircraft gas turbine engine datasets and simulation datasets are presented to demonstrate the framework's superiority in capturing failure modes and RUL prediction accuracy.

2 - Interactive Resource Allocation and Anomaly Detection via Multi-Agent Reinforcement Learning

Xin Xia, University of Wisconsin-Madison, Madison, WI, United States, Jie Guo, Yujie Ma, Chen Zhang, Kaibo Liu

The proliferation of sensor technologies has enabled real-time monitoring across various domains. However, resource constraints—such as limited bandwidth, energy, and processing capabilities—pose significant challenges for continuous data collection and timely anomaly detection. These constraints necessitate intelligent adaptive sampling strategies that select which data streams to monitor at each time step, balancing the trade-off between detection accuracy and operational costs. This study addresses the challenge of decentralized anomaly detection in systems characterized by a hierarchical System–Region–Stream (SRS) structure. We reformulate the problem as a leader-follower decision-making process, wherein a central controller allocates monitoring resources across regions, and each region autonomously selects data streams for local anomaly detection. To optimize this hierarchical decision-making, we develop a scalable multi-agent deep reinforcement learning (DRL) framework that learns long-term policies, effectively mitigating the curse of dimensionality inherent in large-scale systems. Unlike existing methods that often overlook operational costs, our approach explicitly incorporates these costs into the decision-making process, ensuring a more practical and cost-effective monitoring strategy. Extensive simulation studies and a real-world case study validate the efficacy and applicability of the proposed framework, demonstrating its potential to enhance anomaly detection while optimizing resource utilization.

3 - Cost-Efficient Streaming Estimation via Multihypothesis Sequential Transfer

Qunzhi Xu, New York University, New York, NY, United States

We introduce an adaptive sequential transfer learning framework for real-time parameter estimation in streaming environments with multiple candidate source models. Our approach consists of two stages: first, we perform multihypothesis sequential testing to identify the source distribution closest to the target stream; second, we estimate the target parameter using a penalized estimator anchored at the selected source. This procedure balances bias from source mismatch with variance due to limited target data, enabling accurate and efficient estimation under cost constraints. We provide theoretical guarantees under Gaussian designs and demonstrate the method's performance through simulations, highlighting its utility for dynamic monitoring and diagnosis in nonstationary settings.

4 - Rampseg: a Robust Calibration-Free Image Segmentation Method for Reliable Melt Pool Analysis in Laser Powder Bed Fusion

Nazmul Hasan, The University of Arizona, Tucson, AZ, United States, Eung-Joo Lee, Andrew Wessman, Mohammed Shafae

Coaxial monitoring of the melt pool, the molten region formed during laser exposure in laser powder bed fusion (LPBF) additive manufacturing, is critical for ensuring part quality, as its morphology reflects process stability. However, melt pool images are inherently stochastic due to variations in processing conditions, imaging setups, and transient phenomena such as spatter. The impact of this variability on segmentation accuracy has not been thoroughly explored in the literature, resulting in a critical gap in the development of robust methods. As a result, existing segmentation techniques often lack the generalizability and reliability needed to perform consistently across diverse conditions. In response, we propose *RAMPSEg* (Robust Adaptive Melt Pool Segmentation) algorithm, an intensity-agnostic and calibration-free edge-detection-based method that introduces three key innovations: (i) data-driven optimization of edge detection parameters, (ii) a quantitative segmentation review using an edge-to-area ratio to guide refinement, and (iii) an adaptive smoothing feedback loop. Unlike prior methods, *RAMPSEg* avoids arbitrarily selected parameters, over- or under-segmentation, and fixed heuristics. Instead, it achieves self-regulating segmentation that dynamically balances noise reduction and boundary preservation across diverse imaging conditions, enabling more generalizable melt pool analysis. We comprehensively evaluated its effectiveness using three distinct datasets encompassing diverse process conditions, materials, machines, and imaging systems. This unprecedented evaluation demonstrated consistently high segmentation accuracy (~90%) against expert-annotated ground truth, significantly outperforming conventional thresholding, Otsu's method, and state-of-the-art zero-shot vision transformer models (SAM and CLIPSeg). *RAMPSEg* enables reliable melt pool segmentation under dynamic conditions, supporting accurate anomaly detection, process optimization, and quality assurance.

Statistical Models with Manifold-valued Random Objects

Invited Session

Quality, Statistics and Reliability

Chair: Xiaoyu Chen, University at Buffalo, Buffalo, NY, 14260, United States

Co-Chair: Yingyan Zeng, University of Cincinnati, Cincinnati, OH, United States

1 - Differentially Private Geodesic and Linear Regression

Cheng Wang, University of Massachusetts Amherst, Amherst, MA, United States, Carlos Soto

In statistical applications it has become increasingly common to encounter data structures that live on non-linear spaces such as manifolds. Classical linear regression, one of the most fundamental methodologies of statistical learning, captures the relationship between an independent variable and a response variable which both are assumed to live in Euclidean space. Thus, geodesic regression emerged as an extension where the response variable lives on a Riemannian manifold. The parameters of geodesic regression, as with linear regression, capture the relationship of sensitive data and hence one should consider the privacy protection practices of said parameters. We consider releasing Differentially Private (DP) parameters of geodesic regression via the K-Norm Gradient (KNG) mechanism for Riemannian manifolds. We derive theoretical bounds for the sensitivity of the parameters showing they are tied to their respective Jacobi fields and hence the curvature of the space. This corroborates recent findings of differential privacy for the Fréchet mean. We demonstrate the efficacy of our methodology on the sphere, $\mathbb{S}^2$ and, since it is general to Riemannian manifolds, the manifold of Euclidean space which simplifies geodesic regression to a case of linear regression. Our methodology is general to any Riemannian manifold and thus it is suitable for data in domains such as medical imaging and computer vision.

2 - Dynamic Shape State Space Modeling with Regime Switches

Daniel Qiu, Department of Industrial and Systems Engineering, University of Washington, Seattle, WA, United States

We present a novel dynamic state model for shape evolutions with regime changes, where the shape of an object evolves based on control inputs, and the evolution dynamics switch intermittently at unknown instances. Our primary motivating application is modeling shape evolution in additive manufacturing. This research problem is challenging due to the non-Euclidean nature of the shape space, as well as the non-linearity and regime switches in modeling shape sequences. Explicitly modeling this incurs a complicated model and requires estimating a large number of parameters. Therefore, we seek a local approximate estimation for the regime-switching shape dynamics. We establish algorithms and derive open form expressions for parameter estimates. The new approach is tested using benchmark datasets generated from control experiments in additive manufacturing.

3 - Statistical Quality Control with Distributions-Valued Samples

Yingyan Zeng, University of Cincinnati, Cincinnati, OH, United States, Yujing Huang, Xiaoyu Chen

Shewhart control charts were designed to monitor the change in moments (e.g., sample mean, sample standard deviation, etc.) of the observations in a sample. While the natural method to represent the randomness of such observations is based on the probability distribution they follows, limited by the Euclidean spaces where conventional statistics are defined, existing control charts cannot directly monitor probability measures that belong to a metric space referred as 2-Wasserstein space. We argue that moments are insufficient to represent the shape information of the distributions, hence proposing to directly monitoring the samples as random distributions in 2-Wasserstein space. We focus on the optimal transport map T_i which transforms distribution-valued sample μ_i to an in-control Fréchet barycenter $\bar{\mu}$. We prove that T_i preserves an isometric expansion onto a finite set of orthonormal basis functions, which allows us to monitor the change of distribution by the change of basis coefficients over time. Leveraging this theoretical results, we construct the Phase II statistics Hotelling's T^2 and Squared Prediction Error (SPE) via Functional Principle Component Analysis. This framework offers a fundamentally new paradigm for process monitoring while retaining fully distribution-free control limits.

4 - Mixed Distribution-in-Distribution-Out Regression

Xiaoyu Chen, University at Buffalo, Buffalo, NY, United States

A few recent studies reported the linear regression models with distribution-valued samples, which have elevated the regression analysis from Euclidean space to Wasserstein space equipped with 2-Wasserstein metric. However, data collected from real systems are usually a mixture of uncertain measurements represented as

probability distributions and certain measurements represented as scalar values. For example, a patient in a standard electronic health record (EHR) system can produce a distribution of blood pressures measurements, and a scalar variable of his/her gender. Such mixed data pose significant challenges to the current regression models. In this research, we proposed a mixed distribution-in-distribution-out regression model with both distributional and Euclidean covariates.

Chair: Neda Zarayeneh, Hitachi America

1 - A Comparison of Deep Reinforcement Learning and Neural Network Based Predictive Maintenance

Jasper Ng, Proof School, San Francisco, CA, United States, Maharshi Dhada

Effective maintenance planning is crucial for industrial operations, minimizing costly failures and resource consumption. This paper introduces and evaluates a novel Deep Reinforcement Learning approach for maintenance scheduling. Instead of traditional statistical or Machine Learning-based Remaining Useful Life estimates to schedule maintenance, this method feeds raw time-series sensor data directly to a Proximal Policy Optimization agent, allowing it to learn optimal maintenance policies by leveraging the complete sensor information. The researchers tested this approach in a simulated multi-machine shop-floor environment using the Commercial Modular Aero-Propulsion System Simulation Jet Engine Simulated Data. The Reinforcement Learning agent was compared against a baseline strategy employing a Recurrent Neural Network to predict time until failure and trigger maintenance accordingly. The results demonstrate the significance of the Deep Reinforcement Learning approach: the agent achieved a substantially lower and more consistent operational cost (48.06 ± 2.66) compared to the Recurrent Neural Network baseline (122.085 ± 34.856) in a simulated shop-floor scenario containing unseen test data. This highlights that continued improvement of Deep Reinforcement Learning methods (e.g. bypassing intermediate Remaining Useful Life predictions) can lead to much more effective and reliable maintenance decisions.

2 - Partial Trajectory Analysis for Diagnosing Sequential Manufacturing Processes

Tsuyoshi Ide, IBM T.J. Watson Research Center, Yorktown Heights, NY, United States, Kohei Miyaguchi

When a product is manufactured through a sequence of individual process steps, such as in semiconductor manufacturing, identifying steps responsible for detected quality issues is challenging due to process heterogeneity, combinatorial complexity, and unpredictable fluctuations in individual steps, among other factors. As a machine learning problem, this cross-process attribution can be formalized as a sequence attribution task, where the goal is to compute the attribution score for each step in the process sequence, given an observed pair of process trajectory X and quality metric y .

While input attribution has been studied extensively in explainable artificial intelligence, few studies address inputs with a sequential structure. To address this limitation, we propose a new framework called Partial Trajectory Analysis (PTA). The key idea of PTA is to quantify the influence of each process on y by comparing prediction outcomes for partial process trajectories, including and excluding the target process step. For a fair comparison, we solve an optimization problem such that the downstream trajectory follows the optimal path.

We validate the PTA framework using real-world semiconductor fabrication data from a state-of-the-art front-end-of-line process.

3 - Censored Contextual Bandits for Resource-Constrained Maintenance Scheduling

Yipu Yao, Durham University Business School, Durham, United Kingdom, Li Ding, Yanlu Zhao

We consider a preventive maintenance scheduling problem for multiple machines under budget and manpower constraints, where failure data are subject to censoring. Each machine has an unknown failure distribution; maintenance incurs fixed costs, while unplanned failures lead to substantial penalties. The manufacturer's objective is to find an optimal maintenance schedule to minimize the failure losses under limited resources. Since any failures that occur outside the maintenance windows are unobservable, decision-maker must learn from censored feedback. We formulate the problem as a contextual bandit, where each arm corresponds to a maintenance interval and planning tier pair. We then propose a robust learning algorithm that adapts to censored observations and provides finite-sample guarantees and near-optimality under mild conditions. To accelerate convergence, we introduce a global observable boundary condition shared across all machines, which effectively reduces the arm space. Within this framework, we design a decentralized UCB-based scheduling policy that tailors maintenance actions to individual machine characteristics. Numerical experiments demonstrate the effectiveness and robustness of our approach, outperforming benchmark policies in both expected cost and worst-case scenarios.

4 - A Dual-Ema Mean-Teacher for Semi-Supervised Virtual Metrology Under Process Nonstationarity and Variability

Kyeonghui Kim, Yonsei University, Seoul, Korea, Republic of, Chang Ouk Kim

Virtual metrology (VM) often faces limited labels and frequent process nonstationarity and operational variability due to equipment condition changes and preventive maintenance (PM) as well as drift/shift. We propose a dual-exponential moving average (EMA) mean-teacher, which runs two teachers with different EMA momenta (fast/slow) in parallel. Their predictions on weakly augmented inputs are ensembled to form pseudo-targets: the fast teacher reduces tracking lag after changes, while the slow teacher provides a stable reference that damps noise, yielding targets that are simultaneously less delayed and less jittery. The student is trained with supervised mean squared error (MSE) on labeled batches and output-level consistency between strongly augmented student outputs and the ensembled teacher targets on unlabeled batches. Experiment results demonstrate robustness in terms of performance stability and post-change recovery even under the label scarcity and drift/variability commonly encountered in industrial virtual metrology.

5 - Damdg: Degradation-Aware Multi-Domain Generalization for Unseen Hdd Failure Prediction

Jisu Woo, Yonsei University, Seoul, Korea, Republic of, Chang Ouk Kim

Hard Disk Drives (HDDs) are essential components in large-scale storage systems and are equipped with Self-Monitoring, Analysis, and Reporting Technology (SMART), which continuously collects various indicators reflecting disk health. Although machine learning-based approaches for HDD failure prediction using SMART data have been extensively studied, two key challenges remain in real-world applications. First, traditional machine learning approaches typically assume that the SMART data distributions of healthy and failed disks are similar, and that sufficient labeled data are available for training. However, in practice, these distributions vary significantly across HDD models—even among those from the same manufacturer—and previously unseen models are continuously introduced. Second, in failed HDDs, failure symptoms tend to occur briefly and sporadically amid long periods of normal operation, making them both rare and difficult to distinguish from normal patterns. This sparsity and interleaving nature of failure signals hinder the model's ability to learn them effectively. To overcome these challenges, we propose a Multi-Instance Learning (MIL)-based framework that segments each HDD time series into multiple instances and focuses on the most informative segments. Furthermore, we integrate a Multi-Domain Maximum Mean Discrepancy (MMD) loss into an Adversarial Autoencoder (AAE) architecture to minimize distributional shifts across HDD models and to learn domain-invariant representations. Experimental results demonstrate that our method achieves superior failure detection accuracy and improved generalization to unseen HDD models compared to traditional machine learning approaches.

6 - Forecasting Manufacturing Inefficiencies with External Risk Indicators and Data-Driven Modeling

Muhammad Omar Al-Zadid, Washington State University, Pullman, WA, United States

Forecasting manufacturing defect rates is a crucial process improvement and quality control step. Due to the unavailability of direct data on defect rates, this study uses macro-level data on capacity utilization in the U.S. manufacturing sector as a proxy for defect rate, since process inefficiencies are often signaled by significant deviations in capacity utilization. We construct a novel forecasting framework that compares models built on internal operational variables with models enhanced by external risk indicators, including the economic policy uncertainty index, global supply chain pressure index, labor strikes data, and energy input prices for industrial electricity and natural gas. We form a unique dataset from different sources such as FRED, the New York Federal Reserve, the Bureau of Labor Statistics, the Energy Information Administration, and Economic Policy Uncertainty. We combine the data in a monthly panel structure over multiple years and apply various machine learning models, including autoregressive models, random forests, and gradient boosting with cross-validation to compare out-of-sample accuracy. Our study aims to determine whether external risk indicators, in addition to internal operational variables, improve the forecast accuracy of macro-level process performance and provide a scalable, replicable, and public data-driven framework for quality monitoring. This work also bridges the gap between macroeconomic indicators and forecasting manufacturing inefficiencies, offering a unique approach to data-driven performance analysis.

7 - Uncertainty-Aware Load Planning with Deep Learning for the Parcel Service Industry

Thomas Bruys, Georgia Institute of Technology, Atlanta, GA, United States, Reza Zandehshahvar, Amira Hijazi, Pascal Van Hentenryck

In large-scale logistics operations, load plans, which determine when and where shipments will be processed, are essential for ensuring smooth and efficient deliveries. These plans coordinate the flow of goods through processing centers and help allocate resources. However, with the rise of e-commerce, growing uncertainties like delays and demand shifts often require frequent adjustments to the predefined load plans. This study develops a deep learning-based approach to automate inbound load plan adjustments for a large transportation and logistics company. Leveraging over 250,000 historical load records, the study develops a two-stage framework that incorporates uncertainty quantification using conformal prediction. In the first stage, tactical planning, the system predicts the intended processing building and time window for each load a week before operations. This enables early identification of potential plan adjustments and supports efficient resource allocation. The second stage refines these predictions on the day of operation by incorporating real-time data, such as estimated arrival times, which significantly improves the accuracy and adaptability of the system. This dual-stage process balances long-term preparation with short-term flexibility, a crucial capability in high-volume logistics environments. A key innovation is the integration of conformal prediction, which quantifies uncertainty by producing prediction sets with guaranteed coverage, enhancing trust in model outputs. The deep learning architecture employs dedicated embedding layers for both categorical and numerical features, significantly boosting performance on complex tabular data. Experimental results using an industrial dataset show a high prediction accuracy, with substantial improvements for shifted loads in the second stage.

8 - Resilient Part Allocation for Colocation Data Centers Using Multi-Agent AI: An On-demand Optimization Framework

Neda Zarayeneh, Hitachi America, Santa Clara, CA, United States, Pegah Mavaie, Malarvizhi Sankaranarayanan, Omunshu Thapliyal, Ravigopal Vennelakanti

Colocation data centers face a growing challenge in allocating limited critical equipment—such as UPS systems, PDUs, and generators—across 100+ facilities, each at varying phases of development or operation. Unlike retail inventory systems, data center part allocation is constrained by long lead times (up to 150 weeks), variable grid access timelines, and tightly coupled construction readiness schedules. Inefficient inventory management and misallocation of critical equipment, parts, and resources to expansion or new facility projects can lead to overstocking, missed commissioning milestones, and idle capital. With over 30,000 parts to allocate across facilities, operators must manage inventory decisions with precision. We propose a multi-agent AI-based optimization framework that improves allocation visibility, responsiveness, and accuracy across the data center supply chain. The architecture includes an intelligent agent that automates feature extraction from diverse sources, a dynamic classification layer mapping part criticality to construction milestones, and a set of agents that make collaborative decisions under uncertainty. Our system addresses challenges like part delivery misalignment, reallocation delays, and schedule deviation by incorporating demand signals, delivery buffers, supplier risk scores, and facility readiness in real time. Using scenario simulations and project data from colocation providers, the framework demonstrates approximately 70% reduction in misallocation rate, a 2x improvement in reallocation lead time, and significant gains in fulfillment KPIs such as On-Time, In-Full (OTIF) and Order Cycle Time. Inventory KPIs like Stockout Rate and Inventory Turnover Ratio also improve, reflecting better efficiency and prioritization. This work offers a scalable, adaptive model for resilient infrastructure supply chains.

Data-Driven Approaches to Navigate Human-AI Interactions

Invited Session

Artificial Intelligence

Chair: Agni Orfanoudaki, Oxford University, Oxford, N/A, United Kingdom

1 - Learning to Plan Adaptive Human-AI Interaction

Arlen Dean, Washington University in St. Louis, St. Louis, MO, United States, Agni Orfanoudaki, Mohammad Zhalechian

As algorithmic systems are increasingly adopted in the workplace, a key challenge is structuring their use to support, not undermine, human capabilities. This study explores policies for effective human-AI collaboration in a decision-support context. We propose a reinforcement learning (RL) approach to dynamically plan the level of algorithmic guidance provided to a human decision-maker based on their observed user behavior. Our approach aims to navigate the potential risks of both under- and over-reliance, where users may either overlook valuable insights or become overly dependent on them. We theoretically characterize the performance of our proposed model across varying behavioral dynamics and then validate its effectiveness through a controlled experimental study. Our results show that the proposed RL framework can meaningfully improve decision outcomes while sustaining user learning and engagement. We further use our findings to draw insights into when richer behavioral model-derived policies offer added value for planning human-algorithm collaboration.

2 - AI Insurance for Business Operations

Claudio Sánchez Perez de Amézaga, IESE Business School, Barcelona, Spain, Mihalis Markakis, Agni Orfanoudaki

Artificial Intelligence (AI) systems introduce potential risks during implementation and usage when prediction errors lead to costly failures. Insurance, a critical tool for managing risk in many industries, offers a complementary solution to regulatory oversight by providing financial coverage and incentivizing responsible AI deployment. This work proposes a parametric insurance framework to manage such risks in predictive AI applications, providing financial protection to users. We characterize equilibrium contracts that balance user utility, developer incentives, and insurer profitability, accounting for accuracy-sensitive demand and fixed claim costs. Using Inverse Conformal Prediction to model error distributions, we optimize contract terms to maximize developer income. To empirically validate our findings, we leverage a case study on battery state-of-health estimation.

3 - The Value of Partial Information in Sequential Medical Scanning Decisions

Ali Kaan Kurbanzade, Kelley School of Business, Bloomington, IN, United States, Agni Orfanoudaki, Mohammad Zhalechian

In medical decision-making, practitioners often face trade-offs between waiting and conducting diagnostic scans, particularly in areas such as mammography, biopsy, and CT scanning. Existing models typically assume a binary action space—either waiting or performing an expensive full scan. In this study, we extend these models by introducing additional decision options, including partial scans, to assess their impact on sequential decision-making. Partial scans are assumed to be less costly than full scans but also less accurate. However, they provide more reliable information than simply waiting. We build upon existing POMDP frameworks by expanding the action set beyond the traditional binary choices and present theoretical insights into the value of partial information. To validate our findings, we apply our model to a novel dataset from a partnering hospital, focusing on subarachnoid hemorrhage diagnosis and management.

4 - Conformal Decision Risk Assessment

Wenbin Zhou, Carnegie Mellon University, Pittsburgh, PA, United States, Agni Orfanoudaki, Shixiang Woody Zhu

High-stakes decisions in domains such as healthcare, energy, and public policy are often made by human experts using domain knowledge and heuristics, yet are increasingly supported by predictive and optimization-based tools. A dominant approach in operations research is the predict-then-optimize paradigm, where a predictive model estimates uncertain inputs, and an optimization model recommends a decision. However, this approach often lacks interpretability and can fail under distributional uncertainty - particularly when the outcome distribution is multi-modal or complex - leading to brittle or misleading decisions. In this paper, we introduce CREDO, a novel framework that quantifies, for any candidate decision, a distribution-free upper bound on the probability that it is suboptimal. By combining inverse optimization geometry with conformal prediction and generative modeling, CREDO produces finite-sample risk certificates that are both statistically rigorous and practically interpretable. This framework enables human decision-makers to audit and validate their own decisions under uncertainty, bridging the gap between algorithmic tools and real-world judgment.

Data Mining

Chair: Jaeseung Baek, Northern Michigan University, Marquette, MI, United States

1 - Spatial Adaptive Fused Lasso for Monitoring and Diagnosing Topographic Variations

Jaeseung Baek, Northern Michigan University, Marquette, MI, United States

In this research, we present a new approach for monitoring and diagnosing local topographic variations on the surface topography. Monitoring topographic variations in the surface is crucial for quality engineers since the change in the surface finish is closely related to the performance of products in use. Moreover, surface inspection becomes more difficult when the surface contains local defects that are often concealed due to the high dimensional data structure of the surface image. To tackle this problem, we develop a variable selection-based fault detection and diagnostic approach that selects potentially defective areas on the surface by considering the spatial structure of the surface and residual information. Suspicious areas are then employed to detect anomalies and further utilized to identify defect size, location, and shape for fault diagnosis purposes.

2 - Weighted Adaptive Supervised Multi-Group Canonical Correlation Analysis for Multi-Source Data

Tianhui Wang, Iona University, New Rochelle, NY, United States, Yifan Xie, Myong-Kee Jeong

Integrating multi-source data from diverse equipment and processes is critical for improving the prediction accuracy of key manufacturing parameters, such as critical dimensions, which directly influence the overall quality of the final product. In this context, canonical correlation analysis (CCA) has been widely adopted to enhance the correlation between groups while reducing heterogeneity and noise across data sources. However, existing CCA-based methods focus on modeling inter-source correlations and overlook utilizing output information to enhance predictive performance.

Furthermore, current supervised CCA methods assign equal importance to all group correlations, limiting their capacity to handle low-correlation groups and reducing the predictive accuracy.

To address these challenges, we propose a weighted adaptive supervised multi-group CCA framework that maximizes the sum of correlations between data groups and the output, thereby enhancing the predictive capacity of subsequent models. Adaptive inter-group weighting coefficients are designed to strengthen high-correlation groups while reducing the influence of low-relevance ones, enabling a more focused alignment between each data group and the output.

Experimental results demonstrate that the proposed method significantly strengthens correlations with the output, improves inter-group relationships, and outperforms existing methods in predictive tasks. The method achieves improved computational efficiency when applied to high-dimensional datasets by providing closed-form solutions at each iteration. The proposed method provides an efficient and robust solution for multi-source data integration, particularly in manufacturing processes where quality control and process optimization are critical, while also advancing the theoretical understanding of multi-group CCA.

3 - Multi-Class Support Vector Data Description Fire Monitoring System Using Dynamic TIME Warping Kernel in Different Non-Fire Environments

Omar Alturkistani, Rutgers University, Piscataway, NJ, United States, Taha Alhindi, Jaeseung Baek, Myong Kee Jeong

On a global scale, fire disasters present a serious risk to human well-being and the natural surroundings and infrastructure. Traditional fire detection methods encounter a challenge of data imbalance, with an abundance of non-fire scenario data but limited availability from actual fire incidents, resulting in challenges in building an accurate model capable of detecting various types of fires. Moreover, in real-life situations, sensor data collected from the non-fire scenario may exhibit patterns that fall into more than one class. This specific scenario type, known as nuisance scenarios (e.g., smoking and cooking), shares some characteristics with fire scenarios but is considered non-fire, and neglecting such cases can result in delayed fire detection or trigger nuisance alarms. To address this issue, this paper proposes a novel fire monitoring system based on a multi-class support vector data description with a dynamic time warping kernel, which considers distinct sensor patterns from multiple non-fire scenarios. The developed system is able to effectively detect different fire types without prior knowledge by constructing distinct decision boundaries for different non-fire classes. In addition, the proposed system further considers the temporal dynamic and shape patterns present within sensor signals by incorporating the dynamic time warping kernel function. Experimental results demonstrate the proposed system's superiority over existing methods in detecting different fire types earlier and more accurately with lower false alarm rates in non-fire scenarios.

Chair: Hadis Anahideh, University of Illinois Chicago, Chicago, IL, United States

1 - Individual-Level Model Selection via Local Rashomon Set Exploration

Parian Haghighat, University of Illinois at Chicago, Chicago, IL, United States, Hadis Anahideh, Cynthia Rudin

In high-stakes domains such as finance and criminal justice, model multiplicity—where many predictive models achieve similar accuracy yet differ in their individual-level decisions—poses serious challenges to fairness, reliability, and interpretability. This phenomenon, known as the Rashomon Effect, creates ambiguity in decision-making and undermines trust in algorithmic systems. In this talk, we present a novel framework for individualized model selection that embraces model multiplicity as an opportunity for context-sensitive and ethically aligned decision-making. Our approach leverages the Rashomon set of sparse decision trees, enumerated using the TreeFARMS algorithm, and introduces a nonlinear manifold learning technique—diffusion maps—to uncover intrinsic data geometry and define personalized neighborhoods. For each individual, we select a locally optimal model based on both local calibration accuracy and adversarial robustness, quantified using Sparse Explanation Values (SEV). Through empirical studies on the FICO credit risk and COMPAS recidivism datasets, we demonstrate that our method significantly improves local accuracy, interpretability, and robustness compared to global and clustering-based baselines.

2 - Multi-Interval Risk-Based Pareto Dominance for Water Network Rehabilitation Under Uncertainty

Raghavendra Punugu, The University of Texas at Arlington, Arlington, TX, United States, Uthman Kareem, Jay Rosenberger, Victoria Chen, Mohsen Shahandashti

In multi-objective optimization, the dominance of a solution is usually determined using point estimates on the objectives. However, this approach may result in incorrectly identifying a solution as non-dominated when in fact it is dominated when considering the uncertainty of the estimators. Although a few studies in the literature have considered incorporating uncertainty in multi-objective optimization using confidence intervals, they have done so with simplifying assumptions or with simple properties on the confidence intervals, such as half-width or midpoint of an interval. To overcome the challenges, we propose an Interval Risk-based Pareto dominance (IRBPD) approach for multiple risk measures such as Value-at-Risk, Conditional Value-at-Risk, and standard deviation. The proposed approach is applied to water distribution network rehabilitation to identify a set of non-dominated rehabilitation strategies to enhance network resilience under seismic uncertainty. The results obtained demonstrate the effectiveness of the proposed approach.

3 - Adaptive Multi-Objective Bayesian Optimization for Fair Hyperparameter Tuning

Nazanin Nezami, University of Illinois Chicago, Chicago, IL, United States, Hadis Anahideh, Mohammadsina Almasi

Hyperparameter tuning plays a crucial role in machine learning (ML) model selection, impacting both predictive accuracy and fairness outcomes. While Multi-Objective Bayesian Optimization (MOBO) provides an effective framework for balancing competing objectives, existing MOBO methods do not explicitly guide the search toward fairness-improving hyperparameters, often leading to inefficient exploration and suboptimal fairness-accuracy trade-offs. In this work, we propose a novel fairness-aware MOBO framework that introduces a Pareto-based coordinate selection strategy to dynamically prioritize fairness-sensitive hyperparameters. Our approach also incorporates a feature importance-driven discretization mechanism to refine the search space, ensuring a more targeted and efficient optimization process. Unlike existing fairness-aware Bayesian optimization methods that either penalize unfair solutions or rely on general-purpose multi-objective search strategies, our method actively steers exploration toward fairness-optimal configurations. We evaluate our approach against state-of-the-art MOBO techniques, including ParEGO and EHVI, demonstrating that our method achieves superior fairness-accuracy trade-offs while maintaining computational efficiency. These results highlight the importance of fairness-aware exploration in hyperparameter tuning and establish our approach as a scalable solution for responsible model selection.

1 - Sourcing Innovation and Production: a Mechanism Design Approach

Meng Chen, Southern University of Science and Technology, Shenzhen, Guangdong, China, People's Republic of, Xiaoshuai Fan, Ersin Korpeoglu, Cuihong Li

This study investigates the optimal mechanism for a buyer (she) who simultaneously sources innovation design and production from two suppliers (he). The buyer initially commits to a sourcing mechanism that specifies the rules for selecting the design and assigning production. The sourcing mechanism proceeds in two stages. In the first stage, suppliers exert privately known efforts to develop innovation designs with uncertain values. The buyer then provides bonuses based on her report of the innovation values. In the second stage, she selects one design and assigns production to one supplier, with each supplier privately knowing his own production cost. A key feature of our model is that the value of each innovation design is the buyer's private information - a situation commonly observed in many industries where value assessments are inherently subjective and unverifiable by suppliers. This asymmetric information poses significant challenges in designing effective contracts. Our analysis shows that when innovation values are unobservable, bonus payments - typically secondary to allocation adjustments - become essential for ensuring truthful reporting by the buyer.

Moreover, when the effort cost is high, the mechanism can no longer rely solely on monetary incentives, as in the observable case. Instead, it strategically intensifies allocation distortions under low-value innovations, sometimes to the extent that no supplier is selected for production. This research contributes to the literature by illustrating how the privacy of innovation values reshapes the structure of the optimal procurement mechanism.

2 - AI Supervisors and Human Creativity

Sanjiv Erat, University of California-San Diego, La Jolla, CA, United States, Ping-Chieh Huang

With AI-based tools improving at an exponential pace, the day is perhaps not far off when management of knowledge work and of knowledge workers becomes just another skill that can be performed by AI supervisors. The current study investigate how a person's creative performance is affected by the identity of the feedback giver and the nature of the feedback.

3 - Rank-Oriented Benchmarking of Academic Commercialization

Cagri Ozmemis, Georgia Institute of Technology, Atlanta, GA, United States, Karthik Ramachandran

We introduce a rank-oriented benchmarking framework to evaluate academic commercialization performance, reflecting universities' strategic focus on rankings. Built on the objectivity of Data Envelopment Analysis (DEA), our approach prioritizes relative rank over traditional efficiency scores and reveals a counterintuitive trade-off: institutions can attain better ranks under rank-oriented DEA while appearing less efficient than under standard efficiency-oriented DEA. Compared to averaging-based benchmarking method, our approach offers sharper discrimination among peers, a critical feature for rankings. Applying our framework to the AUTM Licensing Survey, we find that universities distributing effort more evenly across multiple commercialization outputs tend to receive more favorable peer-evaluated rankings under rank-oriented evaluation than under efficiency-oriented evaluation. Notably, institutions affiliated with a University Affiliated Research Center (UARC) receive relatively lower evaluations by their peers specifically due to their affiliation.

4 - Sequential Versus Parallel Search Under Competition

Yufei Zhu, National University of Singapore, Singapore, Singapore, Zhi Chen, Zhenyu Hu

Concept generation and new product development (NPD) are essential for business success, as they enable firms to stay innovative in a highly competitive market. However, due to the inherent uncertainty and complexity of the innovation landscape, it is essential that firms thoroughly search across the space of possible concepts, thereby increasing their chances of discovering a winning idea. In practice, sequential and parallel search strategies represent two fundamental approaches to concept generation and NPD. However, firms oftentimes do not conduct concept generation internally but instead delegate it to multiple external agents, such as suppliers or service providers. In this paper, we ask: in such a competitive, multi-agent setting, should the buyer prefer each supplier to conduct a sequential or parallel search? We employ a contest approach to answer this question. Our analysis reveals that when the unit search cost is high or the maximum number of evaluation opportunities is large, the buyer prefers sequential search. Otherwise, parallel search is preferred.

Keynote

1 - How Can INFORMS Contribute to the Second Quantum Revolution?

Sridhar Tayur, Carnegie Mellon University, Pittsburgh, PA, United States

The Second Quantum Revolution – comprising of Quantum Computing, Quantum Communications and Quantum Sensing – provides unprecedented abilities to improve the human condition, security and sustainability, hence mass prosperity, across the world, in a variety of ways, ranging from improving health (through better diagnosis as well new drug development, via exciting applications of Quantum Machine Learning and Quantum Sensing) as well by improving security (in financial transactions as well as better combat cyber-attacks on critical infrastructure, through Quantum Money and Quantum Communication protocols). It also promises to do so using less energy than purely digital methods, thus providing a sustainable approach to sustainable development in a hybrid quantum-classical future.

Integer Programming, Queueing, Markov Decision Processes, Semi-definite Programs. These are some of fundamental methodologies in Operations Research and Management Science that are used to tackle practical applications from Business (Supply Chain, Finance), Engineering (Communication Networks) and Medicine (Cancer Genomics, Image Recognition). At Tepper Quantum Group, we are exploring the twin questions: (a) what can quantum do for OR/MS and (b) what can OR/MS do for quantum.

In this talk, after a brief introduction to the relevant topics in quantum mechanics, I will present an overview of our progress in (a) Graver Augmented Multi-seed Algorithm (GAMA), a novel hybrid quantum-classical algorithm, for non-linear integer programs, with application to hedge funds, cancer genomics and supply chains; (b) Ising Hardware (Photonics); (c) Queueing analyses for quantum communications (buffering, entanglement switch) and (d) tackling fundamental problems in Quantum Information Science (QIS), such as entanglement detection, via SDP.

1 - Beyond the Hype: Rethinking Text Analysis in the Age of Generative AI**Normand Peladeau, Provalis Research, Montreal, QC, Canada**

In this presentation, we will explore latest advancements in generative AI and large language models (LLMs) and see their contribution as well as limitations for text analytics applications. While the excitement surrounding such new technologies is undeniable, older techniques still provide significant value and may even outperform newer methods in certain contexts. By critically examining the strengths and limitations of both established and cutting-edge approaches, we want to offer a balanced, realistic perspective on the role of recent developments in NLP and AI.

2 - Model and Solve Nonlinear Optimization Problems with Artelys Knitro**Richard Waltz, Artelys, Los Angeles, CA, United States**

Artelys Knitro is the leading solver focused on large-scale, nonlinear (potentially non-convex), optimization problems. Knitro offers both interior-point and active-set algorithms for continuous models, as well as tools for handling problems with integer variables and other discrete structures. This tutorial will introduce the key features of Knitro, and demonstrate how to use Knitro to model and solve optimization problems in various environments. The talk will showcase several instances of nonlinear problems, typically addressed through linear relaxation, yet warranting a direct approach. It will delve into the methodologies and tools employed to tackle these challenges. This tutorial aims at an audience familiar with the basics of mathematical optimization, focusing on practical examples.

Advances in Multiobjective Optimization

Invited Session

Multi Criteria Decision Making

Chair: Margaret Wiecek, Clemson University, Clemson, SC, United States

Co-Chair: Kristen Joyce, Florida Polytechnic University, Lakeland, FL, 33896, United States

1 - Pareto Sensitivity, Most-Changing Sub-Fronts, and Knee Solutions

Tommaso Giovannelli, University of Cincinnati, Cincinnati, OH, United States, Marcos Medeiros Raimundo, Luis Vicente

When dealing with a multi-objective optimization problem, obtaining a comprehensive representation of the Pareto front can be computationally expensive. Furthermore, identifying the most representative Pareto solutions can be difficult and sometimes ambiguous. A popular selection are the so-called Pareto knee solutions, where a small improvement in any objective leads to a large deterioration in at least one other objective. In this paper, using Pareto sensitivity, we show how to compute Pareto knee solutions according to their verbal definition of least maximal change. We refer to the resulting approach as the sensitivity knee (snee) approach, and we apply it to unconstrained and constrained problems. Pareto sensitivity can also be used to compute the most-changing Pareto sub-fronts around a Pareto solution, where the points are distributed along directions of maximum change, which could be of interest in a decision-making process if one is willing to explore solutions around a current one. Our approach is still restricted to scalarized methods, in particular to the weighted-sum or epsilon-constrained methods, and require the computation or approximations of first- and second-order derivatives. We include numerical results from synthetic problems that illustrate the benefits of our approach.

2 - Set-Based Regret and Algorithms for Online Multiobjective Optimization

Kristen Joyce, Florida Polytechnic University, Lakeland, FL, United States, Margaret Wiecek

In online multiobjective optimization (OMO), solutions are computed before the objective functions are revealed. As a result, these solutions are not Pareto for the associated offline multiobjective problem and incur a cost, measured by regret.

Scalar regret and set-based regret are defined for OMO and used to evaluate the performance of the Online Gradient Descent (OGD) Algorithm. Minimizing the scalarized OMO problem, the OGD computes a single solution in every iteration and yields the scalar regret. Minimizing the generational distance or inverted generational distance associated with the OMO problem, the OGD computes a set of solutions at every iteration and yields the set-based regret. Numerical results are presented that highlight the value of set-based algorithms over single-solution algorithms corresponding to scalarized OMO problems. Additionally, an online biobjective application is presented for an autonomous vehicle driving on unknown terrain that minimizes both time elapsed and energy loss.

3 - Synthetic Tradespaces for Tradespace Optimization

Cameron Turner, Clemson University, Clemson, SC, United States

A significant challenge for tradespace optimization is the lack of real world tradespace data. However, through the use of synthetic data, it becomes possible to produce representative tradespace data sets without the need for expensive or proprietary data enabling the study and evaluation of tradespace optimization techniques. Eliminating the need to acquire real tradespace data is a significant accomplishment as the costs associated with acquiring real tradespace data and then curating that data are significant in terms of time, effort and money. In this presentation, a sample application for the generation of synthetic tradespace data is introduced along with the necessary techniques to populate the tradespace with a dataset. This dataset can be explored, and analyzed to reveal interesting applications for the tradespace studies. Ultimately, the tradespace can be subjected to an optimization process to identify solutions to the tradespace optimization problem. The sample problem presented has been used in an academic setting for the last five years to allow students to wrestle with the challenges of optimizing in highly complex, multidimensional, nonlinear, mixed-continuous/discrete tradespaces in a realistic manner, while remaining cost-effective to maintain and update to remain technically current and plausible.

4 - Equity-Driven Workload Allocation for Crowdsourced Last-Mile Delivery: a Biobjective Optimization Approach

Hadi Gard (Charkhgard), University of South Florida, Tampa, FL, United States, Iman Dayarian, Abhay Sobhanan

Crowdshipping, a rapidly growing approach in Last-Mile Delivery (LMD), relies on independent crowdworkers for delivery orders. Building a sustainable network of crowdshippers is essential for the survival and growth of such systems, while their participation is primarily motivated by fair pay. Additionally, the financial well-being of crowdworkers is sensitive to fair compensation, especially for those who depend on crowdwork as their main source of income. Therefore, equitable workload allocation and compensation mechanisms in crowdsourcing platforms will benefit both platforms and crowdworkers. We aim to answer several questions gig-economy platforms interested in fair pay may ask: How to measure equity, assess the cost benefits, and manage potential drawbacks? Our main contribution is the proposal of a practical equity-oriented framework tailored to crowdshipping within an LMD environment. This framework draws inspiration from the real-world operations of a group of crowdshipping platforms and operates in real-time. At its core is a bi-objective optimization process that balances equity and cost, aiming to address the study's main research questions. Built on a theoretical foundation, it enables the use of various equity measures and allows us to identify the equity measure that most reliably explores the trade-offs between cost and equity. We show that even a marginal sacrifice in cost efficiency (e.g., 2.5%) can significantly improve equity, potentially up to 39%. We provide actionable recommendations for practitioners, offering insights into selecting equity measures and workforce management.

5 - On the Nondominated Envelope for Multiobjective Optimization

Margaret Wiecek, Clemson University, Clemson, SC, United States, Herve Kerivin, Rakhi Goswami

Multiobjective optimization problems (MOPs) with parametric right-hand-side coefficients model decision-making problems in the presence of multiple, conflicting objective functions, and under uncertainty. For a parametrized family of general MOPs with a parameter drawn from a convex polytope serving as an uncertainty set, we

introduce the concept of nondominated envelope and examine its properties. Specific results are obtained for the linear case.

6 - A Paradigm Shift in Solving Multi-Objective Integer Programs via Objective Domain Reduction

Lagnajita Basu, University of South Florida, Tampa, FL, United States, Hadi Charkhgard

We propose a paradigm shift in generating the Pareto-optimal frontier for multi-objective pure integer programs by introducing binary-encoding reformulations and systematically reducing the objective function value domains. This leads to a new class of branch-and-bound algorithms, where each node corresponds to a feasibility problem solvable via constraint programming. To demonstrate the effectiveness of the proposed method, we focus on bi-objective optimization problems and provide numerical insights and comparisons across a benchmark set of pure integer programs.

1 - Can Nash Inform Capital Requirements? Allocating Systemic Risk Measures

Zachary Feinstein, Stevens Institute of Technology, Hoboken, NJ, United States, Cagin Ararat

Systemic risk measures aggregate the risks from multiple financial institutions to find system-wide capital requirements. Though much attention has been given to assessing the level of systemic risk, less has been given to allocating that risk to the constituent institutions. Within this talk, we propose a Nash allocation rule that is inspired by game theory. Intuitively, to construct these capital allocations, the banks compete in a game to reduce their own capital requirements while, simultaneously, maintaining system-level acceptability. Sufficient conditions for existence and uniqueness of these Nash allocations are provided with applications provided for the prominent structures used for systemic risk measures in the literature. We demonstrate the efficacy of these Nash allocations with numerical case studies.

2 - Systemic Robustness: a Mean-Field Particle System Approach

Wenpin Tang, Columbia University, New York, NY, United States

This work is concerned with the problem of budget control in a large particle system modeled by stochastic differential equations involving hitting times, which arises from considerations of systemic risk in a regional financial network. Motivated by Tang and Tsai (Ann. Probab., 46 (2018), pp. 1597–1650), we focus on the number or proportion of surviving entities that never default to measure the systemic robustness. First we show that both the mean-field particle system and its limit McKean-Vlasov equation are well-posed by virtue of the notion of minimal solutions. We then establish a connection between the proportion of surviving entities in the large particle system and the probability of default in the McKean-Vlasov equation as the size of the interacting particle system N tends to infinity. Finally, we study the asymptotic efficiency of budget control in different economy regimes: the expected number of surviving entities is of constant order in a negative economy; it is of order root N in a neutral economy; and it is of order N in a positive economy where the budget's effect is negligible.

3 - Systemic Risk Measures: Convexity and Beyond

Çağın Ararat, Bilkent University, Ankara, Turkey

In the literature, systemic risk measures have been introduced as multivariate functionals that calculate acceptable capital allocations for an interconnected financial network. The convexity properties of these functionals are determined both by the aggregation mechanism of the network as well as the acceptability rule for the aggregate quantities. In this talk, we present a duality approach to calculate minimum capital allocations for financial networks under concave aggregation mechanisms and convex acceptance sets. Then, as an example of a non-convex systemic risk measure, we consider the case where the acceptance set is that of value-at-risk. In this case, we quantify the lack of convexity for the set values of the systemic risk measure and provide an upper bound on it.

4 - Dynamics of Cascading Losses in Stochastic Networks

Hamed Amini, University of Florida, Newberry, FL, United States

We study risk processes and cascading defaults in large financial networks that exhibit a locally tree-like structure in the limit. Our analysis extends the classical threshold contagion model by incorporating capital growth, allowing us to examine how a firm's default influences its neighbors and potentially triggers a network-wide cascade. We consider a range of network models, including random regular graphs and general continuous-type inhomogeneous random graphs, to explore the interplay between network topology and risk propagation. We also assess the network's resilience to the initial default of a single node, extending existing resilience frameworks to accommodate dynamic thresholds with capital accumulation.

5 - Incomplete Market Equilibrium with Relative Consumption Criterion: a Mean-Field Game Approach

Marko Hans Weber, National University of Singapore, Singapore, Singapore

We study the general equilibrium of a pure-exchange economy with a continuum of agents who face uninsurable income risk, trade dividend-paying stocks, and engage in mutual borrowing and lending. Agents hold "keeping up with the Joneses" preferences and differ in their risk aversion, time preferences, and relative consumption concerns. Each agent's utility depends not only on their own consumption but also on a weighted average of others' consumption, captured through a weighting kernel. We formulate the equilibrium as a mean-field game and derive a closed-form solution. Finally, we show that the resulting mean-field market equilibrium arises as the limit of equilibria in finite-agent economies as the number of agents tends to infinity.

Funding Opportunities for Data Science Research

Panel Session

Committee's Choice

Co-Chair: Ying Lin, University of Houston, Houston, TX, United States

Co-Chair: Mohammad Bisheh, Georgia Institute of Technology, Atlanta, GA, United States

1 - Moderator Panelist

Mohammad Bisheh, Georgia Institute of Technology, Atlanta, GA, United States

This panel session aims to provide INFORMS members with critical insights into navigating the competitive landscape of data science research funding. Panelists, including representatives from major federal funding agencies like the National Science Foundation (NSF) and the National Institute of Standards and Technology (NIST), alongside experienced academic researchers, will discuss current funding priorities, key program initiatives, and anticipated future directions at the intersection of data science, operations research, statistics, and industrial engineering. The session will cover practical advice on crafting compelling proposals, understanding review processes, and identifying relevant funding opportunities across different agencies. Attendees will gain valuable perspectives on how to align their research agendas with national priorities and increase their success rate in securing grants.

Optimization for Transportation Applications

Job Market Showcase

Job Market Showcase

Chair: Myungeun Eom, Georgia Institute of Technology, Atlanta, GA, United States

1 - Flow Optimization and Coordination for Self-Driving Vehicles in Urban Street Networks

Xiaochen Shi, ISyE Georgia Tech, Atlanta, GA, United States, Anton Kleywegt

Infrastructure guided self-driving (IGSD) technology raises the potential to control the path and speed of IGSD vehicles in such a way that traffic flow efficiency is greatly improved. IGSD vehicles approaching the same intersection are grouped into batches based on non-conflict phases, each of which traverses the intersection without stopping. The greater challenge is to factor into the knock-on effect among intersections, and to create a coordinated solution for IGSD vehicle flow to maximize network performance. We propose a Network Batch Algorithm for 100% IGSD street networks, which determines the velocities of vehicles in such a way that no vehicle has to stop while traversing the network, and that minimizes the total delay. An Access-control (AC) method is also developed to reduce the knock-on effect and consequent gridlock, which can be applied with most traffic controls with minor modification. The approaches are experimented in a dynamic setting with the open-source simulator SUMO for Sioux Falls network and compared with benchmark traffic management schemes. The numerical results demonstrate that Batch algorithm with AC method significantly outperforms other traffic management schemes and increases the throughput of the network by 45%.

2 - Urban Delivery with a Coordinated Fleet of Trucks and Drones

Wenjia ZENG, The Hong Kong University of Science and Technology, Hong Kong, China, People's Republic of, Hai Yang, Hai Wang, MINGYAO QI

With the rapid growth of urban delivery demand due to the fast expansion of e-commerce and urban logistics, the recent development and popularization of unmanned aerial vehicles--drones--have attracted increasing attention from large retailers and logistics companies that seek to use drones in urban delivery. In this paper, we study an urban delivery system with a coordinated fleet of trucks and drones, in which multiple trucks deliver parcels and are resupplied by multiple drones at meeting points. We formulate the coordinated delivery problem as a mixed-integer programming model and propose a novel joint assigning, meeting, and scheduling (JAMES) framework that efficiently yields exact solutions when complete information is available. To the best of our knowledge, this is the first exact method to solve the delivery problem with multiple trucks resupplied by multiple drones. We introduce a novel dynamic programming algorithm embedded in an optimal strategy for time scheduling to accelerate the solution. To accommodate an online environment with dynamically arriving orders, an online policy is deployed to make recurrent decisions. Computational experiments show that the JAMES framework significantly outperforms a commercial solver in computational time, solution quality, and scale. The case study on the dynamic framework demonstrates that the online policy generally outperforms traditional greedy heuristics. Evaluation results for a real-world data set demonstrate the benefits of a coordinated fleet, which are particularly evident when transportation resources are limited, because it can increase drone usage and improve the overall service rate.

3 - Dynamic Non-Bipartite Matching in Transportation

Myungeun Eom, Georgia Institute of Technology, Atlanta, GA, United States, Alejandro Toriello

We study a dynamic non-bipartite stochastic matching problem, where nodes appear following a type-specific independent distribution and wait in the system for a given sojourn time. This problem is motivated by applications in ride-sharing and freight transportation marketplaces, and is related to other on-demand marketplaces. We study the asymptotic properties of two widely used policies, batching and greedy, by analyzing a single-pair case and then converting to the general counterpart using a fluid relaxation and randomization. Finally, we present a computational study simulating freight transportation and ride-sharing marketplaces to assess the empirical effectiveness of the policies. We show that the batching policy is asymptotically optimal with respect to the sojourn time; similarly, while a straightforward greedy policy may not be optimal, a greedy policy with randomized modifications is asymptotically optimal. Perhaps more practically relevant, both policies converge exponentially fast to approximate optimality. We also extend our model to an impatient setting in which each unmatched node leaves at the end of each period with a type-dependent probability. We show that the results for the two policies still hold under different assumptions about the nodes' patience; roughly speaking, the batching policy requires more patient nodes than the greedy policy to remain optimal. Our results suggest that managers can achieve near-optimal performance by using simple greedy or batching policies, with only a reasonably small maximum waiting time guarantee, and even in the presence of potentially impatient nodes.

1 - Pleasure OR Peril? the Rise of Online spORts Gambling and Its Mental Health Impact**Jiayuan Tian, University of Florida, Gainesville, FL, United States, Guohou Shan, Michael Rivera, Liangfei Qiu, Md Mahmudul Hasan**

The rapid growth of online sports gambling following its legalization in 2018 has outpaced scholarly attention, fueling ongoing public debate about its broader consequences. Although online sports gambling can serve as a form of entertainment—bringing joy and temporary mood boosts, which we refer to as the pleasure effect—it could also intensify gambling disorders that negatively affect mental health, known as the disorder pathway effect. Our study addresses this ambiguity by exploiting a natural experiment and empirically investigating the impact of online sports gambling on mental health using a unique nationally representative panel dataset. Our findings show that online sports gambling deteriorates the mental health of local residents by approximately 3% on average, primarily by exacerbating gambling disorders. We further examine the heterogeneous treatment effects, uncovering a pronounced disorder pathway in rural areas among individuals with existing addiction. At the same time, we identify a weaker disorder pathway effect in regions with higher education levels and better access to primary healthcare. These findings indicate the uneven impacts of online sports gambling due to social and economic factors. Our study has practical implications for both digital gambling platform holders and policymakers to build sustainable online gambling platforms through targeted regulations that mitigate harm. This study complements the IS literature by addressing the underexplored domain of online sports gambling, an emerging Internet-enabled service. From a theoretical perspective, it also contributes to studies on behavioral health economics and digital gambling ecosystems by uncovering causal pathways that link online sports gambling to mental health outcomes.

2 - The Unintended Consequences of Quota-Based Policy on Content Moderation Efficiency: Empirical Evidence from Online Health Platform**Chen Jie, Arizona State University, Tempe, AZ, United States, Kan Xu, Tongxin Zhou, Pei-yu Chen**

Online Health Question-Answer Platforms (OHQPs) provide accessible and timely health information, improving health literacy and promoting equity. However, these platforms face significant moderation challenges due to limited human resources, high inquiry volumes, and the risks of misinformation. To address these issues, some OHQPs have introduced quota-based moderation policies that limit the number of user inquiries. While prior studies suggest quotas can alleviate congestion in other domains, their effectiveness in health information settings remains unclear. This study evaluates a quota-based policy implemented on a leading OHQP focused on HIV-related concerns. Leveraging a natural experiment and constructing a month-level panel dataset spanning one year before and after the policy, we compare a treated English forum with a structurally similar Spanish forum unaffected by the quota. Difference-in-differences analysis reveals that the policy reduced question volume by 67.4% and responses by 68.0%, accompanied by a 13.5% decline in the response rate and no improvement in response time—indicating no gains in moderation efficiency. Textual analysis further reveals behavioral mismatches: moderators increasingly emphasized community rules and politeness marker (e.g., “please,” “thank you”) while referencing fewer health-related topics (e.g., “illness, sexual and users submitted longer, more socially oriented inquiries with greater use of pronouns like “you” and “they,” suggesting attempts to demonstrate community awareness. This study contributes to the literature by providing one of the first empirical evaluations of quota-based moderation in online health platforms, revealing how scarcity policies can unintentionally degrade platform efficiency by misaligning user and moderator behaviors.

3 - How Consumer-Facing Digital Technologies Shape Productivity in High-Stakes Services: Evidence from Kidney Transplantation**Shujing Sun, University of Texas at Dallas, Richardson, TX, United States, Mehmet Ayyaci, Yeongin Kim, Srinivasan Raghunathan, Bekir Tanriover**

Consumer-facing digital technologies allow service users to access information, interact with providers, and participate in decisions. While such technologies have improved service delivery in industries like retail and finance, their role in healthcare is less clear. Healthcare features greater information gaps and shared responsibility between patients and providers, which complicates how and when technology creates value. Motivated by this uncertainty, we study the effect of patient portals—digital tools that provide patients with access to health records and secure messaging—on service efficiency and patient outcomes in kidney transplantation. This setting involves long waits, limited supply, and time-sensitive decisions, making it well-suited for evaluating the value of patient-facing digital technologies. Using national data on transplant patients linked with hospital-level information on portal availability, we examine the impact of portal access on wait time, health status at transplant, and survival after transplant. We find that portal access shortens wait time and improves patient health at the time of transplant. Features that support communication and information access, rather than administrative tasks, are the main drivers of these benefits. The effects are larger for patients in areas with better internet coverage and lower social vulnerability. We also show that improved health at transplant helps explain why portal users have lower post-transplant mortality. Our findings demonstrate how patient-facing technologies can improve process and clinical outcomes in complex care settings, while also highlighting how digital access and social context shape their effectiveness.

4 - Healthcare Under New Ownership: Does Private Equity Improve Healthcare Value?**Minghong Yuan, The University of Texas at Austin, Austin, TX, United States, Wen Wen, Indranil Bardhan**

In recent years, the healthcare sector has experienced a significant increase in private equity (PE) investment. However, the overall impact of such investment on healthcare performance remains insufficiently understood. This study examines the impact of PE investment on healthcare value, focusing on the complex interplay between operational efficiency and patient care quality. While PE firms often prioritize cost-cutting strategies and operational efficiencies to enhance profitability, these financial objectives may conflict with the core mission of healthcare: delivering high-quality and patient-centered care. Using a difference-in-differences approach, we analyze data from U.S. hospitals, assessing changes in healthcare value, defined as the balance between clinical resource use and patient outcomes, following PE investment. We find that overall healthcare value declines after PE investment. We also examine the moderating role of IT-enabled health information sharing and find that robust information-sharing capabilities can mitigate the negative effects of PE ownership. Specifically, hospitals with strong information sharing experience greater reductions in operating costs and improvements in care quality, resulting in higher post-investment care value. Further analysis reveals heterogeneity in the effect of information sharing based on provider type. By distinguishing between hospital-to-hospital and hospital-to-ambulatory provider information sharing, we find that improvements in care quality are primarily driven by enhanced data exchange with ambulatory providers. These results highlight critical need to align investors interest with patient outcomes and point to the importance of supportive policies that encourage investment in health information sharing to preserve healthcare value under PE ownership.

1 - Exploring the Construction of Local GenAI Governance: a Case of Higher Education Professionals**Rui Sun, New York University, New York, NY, United States**

Generative artificial intelligence (genAI) technologies pose new challenges to AI governance in knowledge work. Aspects of genAI adoption render some traditional governance strategies ineffective. Risks are recognized but difficult to monitor or control. How do knowledge professionals deal with this new reality? How do they construct and mitigate genAI-related risks? This study investigates these questions in the context of higher education, whose core functions of teaching and learning are immensely impacted by students' adoption of genAI tools. I conducted a multi-year inductive qualitative field study of a higher education organization since the emergence of ChatGPT in 2022, focusing on how instructors construct acceptable and unacceptable student AI use in class, and how their local AI governance strategies emerge and evolve through time. Drawing on the social construction of risk object framework, I explicate how various genAI adoption practices in teaching and learning can be constructed as posing harm to the work of higher education professionals. I also illustrate how the professionals try to mitigate the perceived genAI risks by

constructing different local policies and work adaptations. This study presents an effort to explore the emerging practices of genAI governance in knowledge work. It contributes to research on AI governance by showing how aspects of technology adoption and aspects of knowledge work influence the local governance of AI risks.

2 - When Systemic Biases Taint Algorithms: A Path to More Equitable Access in Healthcare

Ozgur Aksoy, The University of Texas at Dallas, Richardson, TX, United States, Mehmet Ayvaci, Asunur Cezar, Srinivasan Raghunathan

Predictive algorithms hold promise for improving resource allocation decisions in socially critical contexts, yet they often exhibit algorithmic bias, inadvertently favoring the socially advantaged. Existing mitigation strategies typically focus solely on correcting predictions, neglecting downstream effects on subsequent decisions and the societal disparities that perpetuate this bias. We investigate the effects of algorithmic bias arising from societal disparities within an integrated prediction–decision framework. Specifically, we assess how explicitly incorporating social factors into prediction–decision pairs influences outcomes, particularly in the context of a healthcare payer’s decision to allocate care management programs to beneficiaries at risk of high costs. We develop an analytical and empirical model of the payer’s allocation decision, and compare outcomes when predictions are adjusted using social factors versus when they are not. While such adjustments can mitigate the negative impact of algorithmic bias at the prediction stage, reducing bias does not necessarily mitigate disparities in decision outcomes—especially when intervention effectiveness varies significantly across social groups. Moreover, tight budget constraints on intervention can diminish the value of adjustments for outcome disparity reduction. Using Medicare insurance payments and CDC Social Vulnerability Index data, we develop a predictive algorithm, quantify algorithmic bias, and demonstrate that our method enhances fairness—intervening on 16.56% more disadvantaged beneficiaries—while preserving decision efficiency. Although we focus on health insurance, our approach is applicable to other socially and economically significant domains within and beyond healthcare.

3 - Responsible AI in Critical Care: Toward Trustworthy Clinical Decision-Making

Tongnian Wang, The University of Texas at San Antonio, San Antonio, TX, United States

Artificial intelligence (AI) is transforming clinical decision-making with the growing use of electronic health records (EHRs). However, ensuring outcomes that are both equitable and accurate remains a critical challenge. Biases embedded in EHR data, as well as those introduced during machine learning (ML) model development, can lead to algorithmic bias, resulting in outcomes that disproportionately harm disadvantaged groups. Efforts to mitigate these biases require diverse and representative datasets, yet strict privacy regulations and data-sharing restrictions make this extremely challenging. Federated learning (FL) offers a privacy-preserving solution by enabling healthcare organizations to collaboratively train ML models without sharing sensitive patient data. However, FL introduces additional challenges in mitigating bias and ensuring robust model performance across diverse clinical settings. Bridging these gaps is crucial to align with the ethical principles of maximizing benefit and minimizing harm. To tackle these issues, we introduce FairPFL, a fairness-aware personalized FL framework designed for clinical prediction with EHRs. Our experiments on real-world EHR datasets demonstrate that FairPFL significantly reduces algorithmic bias while maintaining superior predictive performance, outperforming baseline methods in fairness and performance.

4 - A Novel Fairness-Aware Federated Learning Method in Algorithmic Hiring

zejian wu, University of Utah, SLC, UT, United States, Paul Hu, Da Xu

Algorithmic hiring systems are increasingly adopted in organizational decision-making processes, ranging from sourcing algorithms to identify potential applicants for job openings, selecting resumes for initial screening, and ultimately choosing the final candidate. These systems present significant challenges in ensuring fairness across diverse demographic groups while maintaining privacy and addressing data heterogeneity across various hiring platforms. This study introduces a novel fairness-aware federated clustering method with control variates (FAFC-CV) to address these challenges during candidate selection. By incorporating a demographic parity term into client-specific loss functions and leveraging dynamic clustering, our method effectively mitigates fairness disparities while accommodating the unique characteristics of data from diverse hiring platforms. Theoretically, the proposed method ensures fairness improvements with mathematical guarantees across client groups. Extensive empirical evaluations on real-world hiring datasets demonstrate significant fairness enhancements compared to existing algorithms, with comparable or superior predictive accuracy. This research advances the development of ethical AI by offering a scalable framework for fair and effective algorithmic hiring.

1 - Rural School Bus Routing and Scheduling

Prabhat Hegde, Dartmouth College, Hanover, NH, United States, Vikrant Vaze

Long school bus rides adversely affect student performance and well-being. Rural school bus rides are particularly long, incentivizing parents to drive their children to school rather than to opt for the school bus. This in turn exacerbates the traffic congestion around schools, further compounding the problem of long bus rides, creating a vicious cycle. It also results in underutilized school buses and higher bus operating costs per rider. To address these challenges, this paper focuses on the design of rural school bus routes and schedules, a particularly challenging problem due to its unique operational complexities, including mixed loading and irregular road networks. We formalize a rural school bus routing and scheduling model that tackles these complexities while minimizing the total bus ride time of students. We develop an original road network-aware cluster-then-route heuristic that leverages our problem formulation to produce high-quality solutions. For real-world case studies, our approach outperforms status quo solutions by reducing the bus ride times of students by 37-39 %. Furthermore, our iterative routing and scheduling approach can improve school bus use by 17-19 % and reduce car trips that induce congestion near schools by 12-17 %. Many rural school districts share the operational characteristics modeled in this study, suggesting the broad applicability of our approach. Ultimately, by reducing student travel times, increasing school bus utilization, and alleviating congestion near schools, our approach enables rural school district planners to address transportation-related barriers to student performance and well-being.

2 - Enhancing Supply Chain Decisions to Increase Reliable and Affordable Water Access by Adapting the Inventory Routing Problem and Allocating Costs to Consumers

Emerald Dudzinski, Virginia Tech, Blacksburg, VA, United States

This work optimizes supply chain decisions—inventory management, delivery scheduling, and vehicle routing—to enhance reliable access to safe drinking water for underserved communities. Additionally, we examine affordability and cost allocation to support sustainable operations. Partnering with a nonprofit, we leverage community-representative data and expert validation to ensure practical, scalable solutions.

3 - Modeling Forced Criminality and Intervention in Sex Trafficking Using Multi-Follower Bilevel Optimization

Xiaowei Guo, Clemson University, CLEMSON, SC, United States, Thomas Sharkey

We propose bilevel programming models to analyze sex trafficking networks involving multiple forced illegal activities, with traffickers being the upper-level and victims being the lower-level. The trafficker assigns quotas for victims while aiming to minimize their total risk, whereas victims aim to fulfill assigned quotas with minimal harm. Given that the lower-level victim problems may have multiple optimal solutions, we examine both optimistic and pessimistic bilevel formulations. We propose a novel approach to reformulate the bilevel problem into a single-level problem for both variants of the problem. The pessimistic bilevel problem reformulated by the proposed

method demonstrates a comparable difficulty to the optimistic variant. Experimental results show that our proposed reformulation method better performance compared to the traditional dual-based reformulation approach. We provide insights into how to effectively disrupt these networks.

Empirical Healthcare: Addressing Disparities and Labor Shortfalls in Health Systems

Job Market Showcase

Job Market Showcase

Chair: Maria Ibanez, Kellogg School of Management at Northwestern University, Evanston, IL, United States

1 - Bridging the Nursing Gap: How Virtual Nurse Adoption Mitigates Workforce Shortages and Improves Inpatient Care

Blair Liu, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, Yuqian Xu, Bradley Staats

The growing shortage of registered nurses (RNs) has led hospitals to explore innovative solutions. One such intervention is the Virtual Nurse (VN) model, which enables RNs to perform non-clinical inpatient tasks—such as admissions and discharges—via synchronous video communication. Using encounter-level data from a large healthcare system and a difference-in-differences design, we analyzed nearly 28,000 inpatient cases. VN adoption reduced length of stay (−7.18%) and 30-/60-day readmissions (−2.00%, −1.95%). Mechanism analysis shows improvements stem from shorter clinical service durations, especially when VN support occurs at admission. Effects are stronger under moderate congestion, with experienced VNs, and among high-need patients.

2 - Disparity in Maternal Care: the Role of Operational Factors in Eliminating the Gap

Max Yakovlev, Vanderbilt University, Nashville, TN, United States, Maria Ibanez

Annually, approximately 60,000 U.S. women experience severe maternal morbidity (SMM)—unexpected labor or delivery outcomes with serious short- or long-term health impacts. Many of these outcomes are preventable with appropriate care choices and applications. However, demographic and socioeconomic disparities in obstetric care and outcomes persist, and Black mothers consistently experience higher odds of labor complications. In this paper, we examine how hospital- and physician-level operational factors influence the racial disparity for Black mothers relative to other mothers in the likelihood of (1) riskier delivery procedures (e.g., first-time unscheduled Cesarean Section) and (2) resulting 90-day readmission rates following these procedures. Using cross-sectional data from all labor and delivery admissions across six U.S. states, we uncover key operational factors moderating these disparities: stronger hospital- and physician-level C-section specialization reduces the gap, as does greater exposure to treating Black patients. For instance, the odds of C-section for a Black mother are 11.1% lower when receiving care at a hospital in the top quartile for exposure to Black patients, compared to hospitals outside the top quartile. Notably, hospital ownership also impacts disparities: delivering a baby at a non-profit hospital is associated with lower odds of receiving a first-time unscheduled C-Section for a Black mother, whereas receiving treatment at a government-owned facility corresponds to higher odds of experiencing riskier procedures and 90-day readmissions. These findings highlight the importance of more efficient patient-provider matching, more detailed quality information disclosure, and stronger regulatory oversight. Such measures are crucial to promoting unbiased decision-making and advancing equitable health outcomes.

3 - Training Dilemma: Does More Certified Nurse Assistant Training Lead to Better Nursing Home Outcomes?

Catherine Wang, University of Wisconsin-Madison, Madison, WI, United States, Bob Batt, Hessam Bavafa

Certified Nurse Assistants (CNAs) are essential to the care of residents in nursing homes, yet concerns remain about whether current training requirements are sufficient. This study examines the effect of CNA training hours on nursing home quality and staffing. While federal regulations mandate a minimum of 75 training hours—including both clinical and classroom components—several states have enacted higher standards. The causal effect of these increased training hours on nursing home outcomes, however, remains unclear. Leveraging variation in state training requirements from 2009 to 2017, we use a difference-in-differences approach to estimate the effect of training hours on quality and staffing outcomes. Contrary to policy goals, increased training hours are associated with declines in quality, including an 18.6% rise in deficiency citations and adverse resident outcomes, such as a 3.3% increase in antidepressant medications and a 35.4% decline in reported skin rash cases. We also find shifts in staffing composition, with full-time CNA hours falling by 3.9% and part-time hours rising by 8.6%. These results underscore the complexity of designing effective quality improvement policies and carry implications for addressing persistent quality and workforce challenges in long-term care.

1 - Health Insurance and Labor Productivity: Evidence from US Manufacturing

Yasaman Asayesh, Carlson School of Management, University of Minnesota, Minneapolis, MN, United States, Anant Mishra

Although health insurance is a critical issue at the business-societal interface globally, its impact on labor productivity remains unclear and contested among U.S. practitioners and policymakers. Recent studies suggest that government-sponsored health insurance improves healthcare access for a significant portion of the workforce and may enhance labor productivity. However, the overall impact remains uncertain, as such policies could also reduce work incentives. In this study, we examine how health insurance affects labor productivity in the U.S. manufacturing sector, where nearly one-third of workers rely on public safety net programs. We leverage Medicaid expansion as a quasi-experiment and conduct a difference-in-differences analysis using manufacturing productivity data from 2,554 counties across 49 states between 2010 and 2019. We find a notable positive average effect (3.2% to 4.1%) of Medicaid expansion on labor productivity. These gains are driven by increased manufacturing output rather than reductions in labor input. We further explore the mechanisms behind this effect and find that the productivity gains are not unconditional. Rather, the impact of Medicaid expansion depends critically on local health system capacity. Specifically, we focus on two dimensions: physical infrastructure (e.g., hospital beds per capita) and human resources (e.g., doctors and nurses per capita). Both are necessary conditions for realizing productivity gains. In counties with insufficient health system capacity, we find no significant effects. By identifying the conditions under which health insurance improves labor productivity, our findings offer actionable insights for policymakers seeking to align healthcare access with economic development.

2 - Quality Performance Feedback: the Role of Sequencing Feedback and Female Ownership on Service Outcomes

Peter Thurston Carrera, Fisher College of Business, Ohio State University, Columbus, OH, United States, Aravind Chandrasekaran, Kenneth Boyer

Research shows that performance feedback allows organizations to learn better. This study explores the effects of performance feedback content, sequence, and ownership diversity on learning. We use data from the hospitality industry to investigate these relationships and uncover that sequence and ownership diversity are key to improving service experience outcomes.

3 - Undue Managerial Influence in Selecting Suppliers for Organizational or Supervisory Benefit

Fanny Chen, Rotterdam School of Management, Erasmus University, Rotterdam, Netherlands, Finn Wynstra, Jan van Dalen

While procurement norms explicate that supplier selection decisions should be free from undue influences, buyers often let these decisions be influenced by senior managers. Such undue influences intend to create benefits for the buying organization or manager. When listening to such influence, buyers engage in so-called unethical pro-social behaviors; actions that intend to benefit the organization or its members, but which violate norms and standards. Research has distinguished unethical pro-

organizational behavior and unethical pro-supervisor behavior but has not studied whether individuals behave differently depending on the intended beneficiary. Even though unethical pro-supervisor behaviors may carry a greater risk of sub-optimal results for the organization, unethical pro-organizational behaviors can have negative consequences in the long run too, particularly since affected suppliers may not care about intentions. We investigate whether undue managerial influence aimed at benefiting the organization has different effects on subordinates' supplier selection decisions compared to undue managerial influence aimed at benefiting the supervisor. We conduct two studies, combining between-subject manipulations with discrete choice experiments. The results show that unethical pro-organizational behavior significantly affects supplier selection decisions while unethical pro-supervisor behavior has limited significant effects on buyers' supplier selection decisions. Furthermore, limited significant differences exist between unethical pro-organizational and unethical pro-supervisor behaviors in supplier selection. This suggests that despite earlier arguments that these types of unethical behaviors are fundamentally different, buyers are nearly equally prone to unethical pro-organizational behavior and unethical pro-supervisor behavior. The results also show that moral identity does not curb these behaviors in supplier selection.

1 - Stochastic Optimization with Multimodal Uncertainty and Decision Dependence

Shibshankar Dey, IEMS, Northwestern University, Evanston, IL, United States, Sanjay Mehrotra

Over the past decade, research on decision-making via optimization under distributional ambiguity has seen significant theoretical and computational advances. Recently, this work has expanded to learning-based decision problems that are grounded in optimization techniques while also informed by probabilistic generative modeling advances. Mixture models effectively represent unknown probability distributions, capturing multimodal uncertainties common in data from diverse sources. Motivated by these advances, this talk is organized into two parts.

The first part addresses optimization problems with probabilistic constraints, relevant to highly reliable decision-making under uncertainty. We focus on cases where the underlying uncertainty is modeled by Gaussian mixtures and show how these probabilistic constraints can be reformulated into tractable counterparts with and without distributional ambiguity using Wasserstein-based ambiguity sets.

In the second part, we consider the framework to incorporate decision-dependent forms of moment-based ambiguity sets and reformulate the resulting intractable models into workable forms. We show that state-of-the-art solvers highly underperform for such hard problems, whereas our adaptive approach delivers superior computational efficiency. Thus, this work contributes to both modeling techniques and algorithms for discrete decision-making under decision-dependent uncertainty.

2 - Data-Driven Optimization for Fast and Reliable Decision-Making Under Uncertainty

Irina Wang, Princeton University, Princeton, NJ, United States, Bartolomeo Stellato

Robust optimization and distributionally robust optimization have become widely adopted tools for building solutions that remain effective under uncertainty, but some challenges have always limited their practical functionality: high computational effort in terms of both memory and runtime, conservative models of the uncertainty leading to suboptimal solutions, and complex formulations that require advance knowledge of convex analysis. In this talk, I will address these challenges by discussing new data-driven frameworks for decision-making under uncertainty. In particular, I will focus on reducing data dimensionality to achieve computational speedups, and on learning contextual decision-focused uncertainty sets to reduce model conservatism.

3 - Drift Optimization of Regulated Stochastic Models Using Sample Average Approximation

Zihe Zhou, Purdue university, West Lafayette, IN, United States, Harsha Honnappa, Raghu Pasupathy

This work considers sample average approximation (SAA) of a general class of stochastic optimization problems over a function space constraint set and driven by "regulated" Gaussian processes. We establish statistical consistency by proving equiconvergence of the SAA estimator via a sophisticated sample complexity result. Next, recognizing that implementation over such infinite-dimensional spaces is possible only if numerical optimization is performed over a finite-dimensional subspace of the constraint set, and if sample paths of the driving process can be generated over a finite grid, we identify the decay rate of the SAA estimator's expected optimality gap as a function of the optimization error, Monte Carlo sampling error, path generation approximation error, and subspace projection error.

4 - Leveraging Graph Structure to Optimize Learning Algorithms

Mansi Sood, MIT, Cambridge, MA, United States

As our world becomes increasingly interconnected, the informational landscape that drives decision-making is marked by ever-expanding scale and complex interdependencies. Motivated by computational constraints in emerging computing paradigms, we study how better leveraging structure can push the frontiers of large-scale inference. Through the lens of graphical models, we develop computationally efficient alternatives to canonical subroutines that underlie inference in modern machine learning and optimization infrastructure.

We present our contributions along two key directions. First, we optimize graph algorithms for learning securely from distributed data sources, addressing a key challenge in decentralized settings—namely, identifying simple probabilistic rules for organizing nodes to balance sparsity with reliable connectivity. Our results resolve several open problems related to the exact analysis of connectivity properties in a class of random graph models known as random k-out graphs, widely appearing as heuristics for network design in settings with limited trust. Second, we develop computationally efficient alternatives to parameter estimation in graphical models that retain the statistical guarantees of classical methods like maximum likelihood estimation while significantly cutting computational costs. Our work sheds new light on how the interplay between graph structure and performance can be leveraged to push the frontiers of efficient and provably reliable algorithms.

Chair: Sixiong You, Eli Lilly and Company

1 - Governing Higher Education Accessibility Knowledge Commons

Kyrie Zhixuan Zhou, University of Texas at San Antonio, San Antonio, TX, United States, Madelyn Sanfilippo

Lags in enforcement of Title II and market incentives to design for the majority and maintain default settings lead to significant challenges around accessibility (e.g., inaccessibility of PDF files, proprietary digital textbook platforms that are incompatible with screen readers) for college students with disabilities. In this mixed-methods case study, we combine auto-ethnography, a structured diary study among the authors, and computational content analysis of university policies to understand accessibility of higher education through the lens of Governing Knowledge Commons (GKC). GKC is a descriptive conceptual framework to support the analysis of community

governance of shared knowledge resources. The GKC framework allows us to unpack how shared knowledge and institutional structures are collectively managed to increase or decrease accessibility of higher education. Key action arenas identified in this study include decisions on procurement of accessible technologies (e.g., learning management systems), ineffective accommodations for students, underfunded disability services, overreliance on retrofitting rather than implementing accessibility at the onset, and overpromising of universal design. By identifying common failures in ensuring accessibility, we propose policy and design recommendations to rectify these issues, including: (1) accessibility training for faculty and staff members, (2) ensuring software accessibility in the procurement and operation processes, and (3) applying universal design principles consistently and contextually.

2 - DEI Commitment and Firms Operational Efficiency: Deep Learning Evidence from 300 million Job Posts

Shucheng MIAO, The Hong Kong Polytechnic University, Hong Kong SAR, Hong Kong, Xuemin Luo, Andy Yeung

Problem Definition: Diversity, Equity, and Inclusion (DEI) has become a strategic priority for organizations, yet its operational implications remain underexplored. This study addresses three questions: (1) Do job posts exhibit variations in DEI commitments, and if so, what characteristics lead to stronger DEI commitment? (2) Does DEI commitment relate to firm-level operational efficiency, and under what conditions will such effects be more pronounced? (3) Are these relationships robust to external societal events or regulatory shocks? **Methodology/Results:** Leveraging advanced deep learning BERT and RoBERTa algorithms, we construct a novel DEI commitment measure from over 300 million U.S. job posts, matched with firm-level financials for public firms. We find: (1) DEI language varies systematically across jobs, sectors, and years; (2) moderate DEI commitment enhances OE, especially in large, labor-intensive, and mature firms, but (3) an inverted U-shaped pattern emerges—excessive signaling erodes returns. Exogenous shocks of the BLM movement and Women on Boards Laws (SB-826) in California provide more causal and robust evidence for the inverted U-shaped relationship between DEI commitment and operational efficiency. **Managerial Implications:** DEI signaling can function as a dynamic capability when tuned to internal resources and external context. Yet over-commitment undermines cohesion and operational focus. Our DEI measure offers managers a data-driven deep learning tool to calibrate inclusion efforts: strategic alignment, not symbolic escalation, is key to sustaining operational efficiency performance.

3 - Performance and Misalignment: a Within-Subjects Study of New Role Integration in Hybrid Purpose-Oriented Networks

Xinmeng Huang, Northwestern University, Evanston, IL, United States

Facing more complicated societal, technical and operational challenges, organizations' integration of new external roles into existing teams to facilitate progress, communication, and innovation is becoming a standard and recurring practice. Meanwhile, new network structures, such as Multi-Team Systems, with cross-functional and cross-sector characteristics, are becoming increasingly prevalent. As AI has evolved in its societal role and taken on increasingly prominent responsibilities in high-stakes collaborative contexts, its integration into task-driven organizational settings is inevitable. As more teams in organizations welcome functional colleagues such as AI into their team, however, the impact on the existing teams' dynamics, objective alignments, and performance remains unanswered. Using within-subject designs, we collected data points from students at Northwestern University in a classroom study. Teams made an initial decision without AI, followed by decisions with the integration of AI teammates in different cross-functional network structures. Answers to cognition-based trust questions—inquiries built on rational evaluation of reliability or competence—were collected at the end of each stage. Our data-driven findings show that the integration of AI reduces cognition-based trust, alignments, and performance in existing teams. In contrast to traditional human teams, cognition trust using individual as trust referent is a stronger indicator of team performance than trust using team as trust referent in teams where AI was introduced. These findings lay the groundwork for more in-depth exploration of how integration of new roles, such as AI, influence team dynamics, alignments, and performance.

4 - Visualizing Cyber-Physical Attacks Through Physics-Informed Modeling

Madison Evans, Auburn University, Auburn, AL, United States, Greg Purdy

While connectivity has transformed manufacturing operations, it has outpaced the ability to adequately secure them. The interconnected and highly digitized manufacturing floor introduces unique cyber-physical vulnerabilities that could lead to serious physical consequences. Due to the risk of equipment damage, real-world data on cyber-physical attacks remains limited. To address this challenge, we are developing a Cyber-physical Manufacturing Range (CPMR) — a controlled environment, consisting of a dedicated machine and its digital counterpart. The physical machine informed the creation and movement of the digital replica, which was developed using the Unity real-time platform. However, repeating this process for attack scenarios is limited by the physical risks associated with executing live attacks. To generate realistic attack visualizations across multiple levels of fidelity, we must combine a variety of techniques. In this presentation, we will show how we are using these techniques to create varying types of physics-informed visualizations. We will discuss the shortcomings of those techniques and outline planned improvements to increase realism, scalability, and accuracy.

5 - Efficient Engagement: Opportunities for Mobile Methadone Maintenance in Geographically Underserved Areas

Anthony Bonifonte, Denison University, Granville, OH, United States, Erin Garcia

In 2021 the Drug Enforcement Agency changed regulations to allow easier registration and operation of mobile methadone clinics for treating opioid use disorder in rural and underserved areas. How these routes might best be operated and how many clients might be served by mobile units are open questions. This work identifies candidate dispensing locations from mobile units in areas that do not have geographic access to a fixed clinic. Optimal routes for mobile methadone are identified by solving a mixed integer program that maximizes the number of clients without access to care that can be served by a mobile route. Ohio is used as a case study state to explore the efficiency of routes leaving from each methadone clinic in the state. The approach is generalized nationwide, and multi-vehicle routes are analyzed. Between 48 and 68 clients can be served by a single vehicle in a day (mean of 60) under default parameter assumptions across Ohio. Similarly, nationwide routes serve a mean of 47.5 clients per day. The second and third vehicle routes from a clinic provide access to an additional 95% and 93% of the clients of single vehicle routes, respectively. The number of servable clients on any route greatly differs based on geography. This work demonstrates the potential value of mobile methadone maintenance in reaching populations without geographic access to a fixed clinic. Additional policy and funding changes are needed to incentivize the operation of mobile methadone units for serving rural and unmet demand.

6 - Participatory Objective Design via Preference Elicitation

Ali Shirali, University of California, Berkeley, Berkeley, CA, United States

In standard resource allocation, designers fix the objective function, assuming agents only care about their own allocations. This neglects agents' potential preferences over the objective itself—such as concerns for inequality or altruism—which cannot be captured by standard utility reports. We propose a participatory framework where agents express preferences over possible objectives, and the designer solves a modified problem that combines a benchmark objective with these preferences. We instantiate this in a fair division setting, where agents divide divisible goods and some are inequality-averse. Using the Fehr-Schmidt model, we show that this participatory approach can yield significant welfare gains, with bounded losses in the standard objective. Our theoretical results highlight tradeoffs and suggest that incorporating agents' preferences over objectives can outperform standard approaches in natural settings.

7 - Physics-Informed Predictions of Backorders in a Supply Chain

Sixiong You, Eli Lilly and Company, Indianapolis, IN, United States, Souptik Majumder, David Buchta

Accurate forecasting of back orders is critical for effective supply chain management and production planning. Accuracy is compromised by uncertainty, time delays, hidden variables, and nonlinear effects—common features in real-world supply chain systems. To enhance accuracy, we combine partial historical observations (e.g., supply, consumption, backorders) with physical constraints (conservation of mass for inventory) in a nonlinear dynamical model for backorders. This constraint guarantees physical law and reduces noise from data. The primary nonlinear model considered for demonstration is the Sparse Identification of Nonlinear Dynamical Systems (SINDy). As a data-driven approach that derives explicit ordinary differential equations (ODEs) from historical observations, SINDy provides transparent and parsimonious representations of system dynamics, enabling not only accurate forecasting of backorders but also revealing the underlying mechanisms — such as demand fluctuations and replenishment lags — that drive their evolution over time. This ODE-based formulation with time-delay embeddings is well-suited to capture the temporal dependencies and nonlinear dynamics commonly observed in supply chain systems. We evaluate our approach using a synthetic dataset, emulating a multi-echelon supply chain system, and benchmark it with classical ML models, including Linear Regression, Random Forest (RF), and XGBoost as well as domain agnostic foundational

models such as Chronos (Ansari et al. 2024). Our findings suggest that incorporating physical constraints into data-driven modeling approaches improves performance and contributes to more interpretable representations of supply chain dynamics

Chair: Max Li, University of Michigan, ANN ARBOR, United States

1 - Operational Approaches to Improve the Sustainability of Commercial Aviation

R. John Hansman, Massachusetts Institute of Technology, Cambridge, MA, United States

Operation approaches for reducing fuel burn and persistent contrail formation are the most effective near term response to the worldwide focus on improving the sustainability of air transportation. This presentation will first discuss potential approaches and then a worldwide comparison of 1 year of ADS-B surveillance data with fuel optimal trajectories to identify systemic areas of inefficiency. The analysis shows different mechanisms of inefficiency for horizontal, vertical and speed inefficiencies and variations between world regions. Potential approaches for improving the flexibility of air traffic control will also be discussed.

1 - Dynamic Route Optimization and Automation of Industrial Routes at Wm

Stuart Greene, WM, Houston, TX, United States, Hema Pillutla, Marcel Dalby, Seongbae Kim, Heesu Hwang, Sergiy Savchenko, Chao Zhou

WM, the leading provider of environmental solutions, faced significant challenges in optimizing its industrial waste collection routes following the pandemic. Traditionally, these routes were planned manually, a process that was time-consuming, labor-intensive, and suboptimal with multiple factors that need to be considered. WM has embarked on a journey to develop and implement a dynamic route optimization program tailored to the unique requirements of its industrial waste collection operations. The industrial waste collection sector presents a complex routing problem due to the dynamic nature of the customer service demand, various factors such as customers specific service requirements, container types, sizes, the disposal of waste materials among others. The dynamic route optimization system leverages data analytics, forecasting future service demand for effective capacity planning, advanced algorithms using metaheuristics to automate generation of routes that improve efficiency while ensuring safety and fulfilling customer service commitments. By effectively combining advanced analytics, optimization, and technology led automation for the industrial line of business, WM realized best-ever efficiency gains and operating margins and set the foundations for driving increased value in the future.

2 - Regionalize and Scale: Amazon Network Design for Faster and Cheaper Delivery

Cristiana Lara, Amazon, Bellevue, WA, United States, Ling Zhang, Shahbaaz Mubeen

By the end of 2021, Amazon in the US was selling over a billion items per year, through a network of hundreds of fulfillment centers, each carrying millions of unique items, spread throughout the continental US. These items were delivered through a single national transportation network consisting of internal resources and external delivery partners, leveraging a variety of facilities (fulfillment centers, sortation centers, and delivery stations), that was multi-modal and densely inter-connected. Amazon's proposition of offering Earth's largest selection, fast, with low cost-to-serve, faced challenges as a result of this unprecedented network growth. The need for speed requires systems that make real-time decisions on where to fulfill orders from based on the state of the network and inventory availability, which in turn results in high variability in the set of fulfillment centers (FCs) serving any destination area (e.g. city). That high variability translates to increased costs and reduced speeds.

In 2021, Amazon senior leadership identified this problem and assembled a team, the majority of whom were Operations Research (OR) professionals, to develop a solution. That solution is Regionalization, where we partitioned the US into 8 interconnected but largely self-sufficient regions. The development and launch of Regionalization were the result of 1.5 years of sustained OR studies examining each aspect of Regionalization, leveraging a multitude of OR methodologies such as mixed-integer programming, queueing theory, discrete-event simulation, inventory theory, machine learning, and statistical analysis. Regionalization was implemented in early 2023, and has since resulted in significant cost and speed improvements.

Interpretable AI for Critical Decision-Making

Invited Session

Practice Track

Chair: Lili Zhang, Hewlett Packard Enterprise, Alpharetta, GA, United States

1 - Practices of Improving Accurate Interpretations of Graphrag with Structured and Unstructured Data

Lili Zhang, Hewlett Packard Enterprise, Alpharetta, GA, United States

Graph-based Retrieval-Augmented Generation (GraphRAG) is emerging as a cutting-edge technology that combines the structured relationship modeling capabilities of Knowledge Graphs with the contextual reasoning strengths of Large Language Models (LLMs). This results in a dynamic and efficient system for managing and generating information. However, like other GenAI or RAG applications, GraphRAG can face challenges related to accurate interpretations. In this talk, we will share practices for improving the accurate interpretations of GraphRAG by optimizing knowledge graphs with both structured and unstructured data. These practices are based on experimental comparison results across multiple use cases, such as customer engagements, user activities, and product diagnosis.

2 - Transparency and Interpretability in Supply Chain Inventory Optimization

Fan Wu, Intel, Atlanta, GA, United States, David Bayba

The emergence and swift advancement of AI and large language models (LLMs) significantly enhance the interpretability of supply chain recommendations derived from complex machine learning models. In the realm of inventory forecasting and management, we employed modern machine learning and time series methods to predict consumption over the next nine months and calculate key inventory metrics such as safety stock and reorder points based on these forecasts. Prior to the integration of LLMs, analysts spent considerable time investigating and communicating with stakeholders to ensure recommendations aligned with business practices and to explain the rationale behind forecasts generated from historical consumption patterns. With LLMs integrated into the system, a bot-like application can directly address stakeholders' inquiries by querying the knowledge base—such as databases containing historical consumption data and related features influencing forecasts—and making informed assumptions. Future work involves enhancing the model application to proactively explore and summarize use cases that stakeholders might categorize as anomalies but are currently unaware of. This approach aims to build a more robust inventory system and effectively monitor its overall health.

1 - A Characterization of Reny's Weak Sequentially Rational Equilibrium Through Epsilon-Perfect Gamma-Weak Sequentially Rational Equilibrium and Its Selection

Chuangyin Dang, City University of Hong Kong, Kowloon, Hong Kong, Yiyin Cao

A weakening of sequential rationality of sequential equilibrium yields Reny's (1992) weak sequentially rational equilibrium (WSRE) in extensive-form games, which requires Kreps and Wilson's (1982) consistent assessment to satisfy global rationality of nonconvex functions at every information set reachable by a player's own strategy. The consistent assessment demands a convergent sequence of totally mixed behavioral strategy profiles and associated Bayesian beliefs. Nonetheless, due to the nonconvexity, the existence of WSRE had to invoke the existence of normal-form perfect equilibrium, which is sufficient but not necessary. Moreover, Reny's definition of WSRE contains insufficient information on constructing the convergent sequence. To address these two challenging issues, this paper develops a characterization of WSRE through ϵ -perfect γ -WSRE with local sequential rationality, which is achieved with the introduction of an extra behavioral strategy profile. For any given $\gamma > 0$, we generate a perfect γ -WSRE as a limit point of a sequence of ϵ_k -perfect γ -WSRE with $\epsilon_k \rightarrow 0$. A WSRE is then acquired from a limit point of a sequence of perfect γ_q -WSRE with $\gamma_q \rightarrow 0$. This definition allows one to analytically find all the WSREs for small extensive-form games and directly prove the existence of WSRE. An application of the characterization yields a polynomial system to serve as a necessary and sufficient condition for determining whether a totally mixed assessment is an ϵ -perfect γ -WSRE.

2 - Data-Driven Leader-Follower Game

Bo Zeng, Pitt, Pittsburgh, PA, United States, Zhengsong Lu

In this talk, we present a study on a data-driven leader-follower game where the utility function of the follower is known up to an ambiguity set. By employing the recent methodological development on distributionally robust optimization (DRO), this complex model can be solved efficiently, leading to a reliable solution for the leader, who might be a policy maker for a large number of followers.

3 - Distributed Dynamics and Stable Outcomes in Coalitional Games and Matching

Jeff Shamma, University of Illinois Urbana-Champaign, Urbana, IL, United States, Aya Hamed

Cooperative games model strategic settings in which agents coordinate to form partnerships and share payoffs to achieve mutually beneficial outcomes. These settings range from two-sided matchings to larger groups forming coalitions. A stable outcome is where no subgroup of agents has an incentive to break away to form a separate partnership. Stable outcomes, when they exist, can be computed in a centralized manner, where a single entity has full information about the underlying setup and full authority to assign partnerships and payoffs. Here, we present distributed dynamics where agents both form and break partnerships according to evolving internal aspiration levels that reflect self-interest. Our distributed dynamics require simple computations, limited memory, and most importantly, minimal knowledge of the environment. We establish that these dynamics converge to stable outcomes analogous to the core and present a variety of computational experiments.

4 - Conjectural Online Learning Dynamics Under Model Misspecification

Tao Li, City University of Hong Kong, Hong Kong, Hong Kong

As modern cyber-physical systems grow in scale and intricacy, their principled design, defense, and management depend on appropriate mathematical modeling, based on which computationally efficient operation strategies are developed. The fundamental challenge of this "modeling-then-optimize" paradigm arises from the entanglement between model **misspecification**, which is due to the epistemic uncertainty of the underlying system, and model **approximation**, which is intentionally introduced to trade model fidelity for computation efficiency. This work investigates the entanglement between misspecification and approximation in the context of partially observed Markov decision processes (Markov Games), where a decision-making agent holds a conjectured model of the system environment, which is calibrated using information feedback induced by decisions devised under the approximated conjecture model. The central question we aim to answer is whether the approximation affects model misspecification calibration. We consider Bayesian learning as the canonical approach for online model calibration and belief-quantization as the approximation scheme, and study the asymptotic behavior of the dynamical systems induced by such online learning, referred to as conjectural online learning. We study the self-fulfilling prophecy in conjectural learning dynamics by inspecting its attracting basin.

Foundations of Generative Diffusion Models

Invited Session

Applied Probability Society

Chair: Renyuan Xu, Stanford University, Palo Alto, CA, United States

1 - Data-Driven Generative Simulation of Sdes Using Diffusion Models

Xunyu Zhou, Columbia University, New York, NY, United States, Xuefeng Gao, Jiale Zha

This paper introduces a new approach to generate sample paths of stochastic differential equations (SDEs) using diffusion models, a class of generative AI models commonly employed in image and video applications. Unlike traditional Monte Carlo methods, which require explicit specification of the drift and diffusion coefficients of the SDE, our method takes a model-free approach. Given a finite set of sample paths from an unknown SDE, we propose a data-driven framework that utilizes conditional diffusion models to generate new, synthetic paths of the same SDE. To demonstrate the effectiveness of our approach, we conduct comprehensive experiments on various SDEs and compare its performance with alternative benchmark methods including neural SDEs. Furthermore, we explore the potential of leveraging these synthetically generated sample paths to enhance the performance of reinforcement learning algorithms in continuous-time mean-variance portfolio selection, hinting promising applications of diffusion models in financial analysis and decision-making.

2 - Dimension-Free Convergence of Diffusion Models for Approximate Gaussian Mixtures

Yuting Wei, University of Pennsylvania, PHILADELPHIA, PA, United States

Diffusion models are distinguished by their exceptional generative performance, particularly in producing high-quality samples through iterative denoising. While current theory suggests that the number of denoising steps required for accurate sample generation should scale linearly with data dimension, this does not reflect the practical efficiency of widely used algorithms like Denoising Diffusion Probabilistic Models (DDPMs). In this talk, we investigate the effectiveness of diffusion models in sampling from complex high-dimensional distributions that can be well-approximated by Gaussian Mixture Models (GMMs). For these distributions, our main result shows that DDPM takes at most $O(1/\epsilon)$ iterations to attain an ϵ -accurate distribution in total variation (TV) distance, independent of both the ambient dimension d and the number of components K , up to logarithmic factors. Furthermore, this result remains robust to score estimation errors. These findings highlight the remarkable effectiveness of diffusion models in high-dimensional settings given the universal approximation capability of GMMs, and provide theoretical insights into their practical success.

3 - Generator Matching: Unified Theory for Generative Models

Minshuo Chen, Northwestern University, Evanston, IL, United States

Generative AI has achieved remarkable success in modeling high-dimensional, multi-modal data through techniques such as diffusion models and normalizing flows. However, the theoretical underpinnings of these diverse modeling paradigms remain fragmented and underdeveloped. We close the gap via *generator matching*, a unified framework that encompasses autoregressive modeling in LLMs, denoising score matching in diffusion models and velocity matching in flow-based generative models. By interpreting both as instances of matching the generator of a continuous-time Markov process to model the data, this framework generalizes and extends current approaches to modeling complex, multi-modal distributions. We establish statistical learning theories for generator matching, providing consistency guarantees and generalization bounds. Our theory not only bridges existing paradigms in generative modeling but also opens new avenues for principled design of stochastic processes underlying modern generative models.

4 - Computational Bottlenecks for Denoising Diffusions: An Example of Sparse and Low-Rank Distributions

Viet Vu, Stanford University, Stanford, CA, United States

Denoising diffusions sample from a probability distribution μ

in $\mathbb{R}^d$ by constructing a stochastic process $(\mathbf{x}_t)_{t \in [0,1]}$ in $\mathbb{R}^d$ such that $\mathbf{x}_0$ is easy to sample, but the distribution

of $\mathbf{x}_T$ at large T approximates μ . The drift

$\mathbf{m} : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ of this diffusion process is learned by minimizing a

score-matching objective.

Is every probability distribution μ , for which sampling is tractable, also amenable to sampling via diffusions?

We provide evidence to the contrary by studying a probability distribution

μ for which sampling is easy, but the drift of the diffusion process is intractable ---under a popular conjecture on information-computation gaps in statistical estimation.

We show that there exist drifts that are superpolynomially close to the optimum value

(among polynomial time drifts) and yet yield samples with distribution that is very far from the target one.

Co-Chair: Tao Li, City University of Hong Kong, Yeung Kin Man Academic Building, Hong Kong, N/A

1 - Digital Twins for Transportation and Infrastructure: Accelerating Scenario Creation and Real-TIME Analysis

Ruimin Ke, Rensselaer Polytechnic Institute, Troy, NY, United States

This presentation unifies three recent advances from the speaker's group into a cohesive digital-twin pipeline suitable for campus-scale transportation studies. First, the ChatSUMO agent converts plain-language requests (e.g., "medium traffic within a one-mile radius of Albany") into complete SUMO networks and demand files in a short time, ten-to-fifteen times faster than manual scripting, without requiring simulation expertise. Second, an edge-computing module deploys detection and tracking methods on a Jetson Xavier NX edge computer to detect and track vehicles in real-time, map their 2-D image coordinates into 3-D space, and stream the results to a CARLA-based campus digital model, overcoming occlusion and lens-distortion challenges to maintain a live vehicle layer in the twin. Finally, a CARLA-SUMO co-simulation environment ingests those vision feeds and applies multi-agent Q-learning for adaptive signal timing, providing a test bed that marries realistic rendering with control algorithms. Together, these components demonstrate a practical, data-driven workflow in which analysts can describe a scenario in natural language, populate it automatically, tether it to real-time edge sensing, and evaluate optimization strategies. The talk will discuss methodology, validation results, and lessons in rapidly reconfigurable digital twins aimed at transportation decision support.

2 - Mobility Digital Twin with AI Agents and AI Networks

Xishun Liao, University of Central Florida, Florida, FL, United States

Mobility Digital Twins (MDT) are rapidly evolving into sophisticated tools for simulating and optimizing smart city systems. In this talk, a novel MDT framework built on the integration of the concepts of AI Agents and AI Networks will be introduced. Within this framework, AI Agents serve as intelligent digital replicas of individual entities, such as travelers, drivers, vehicles, capable of learning, decision-making, and generating behavioral patterns at varying resolutions to capture nuanced cross-domain interactions. These agents dynamically adjust to evolving conditions in the AI Networks and can simulate complex behaviors that are critical for realistic mobility modeling. Concurrently, AI Networks represent a multi-layered digital ecosystem that encompasses both dynamic components, such as traffic flows and sensor data, and static elements of the built environment, including roadway networks, point-of-interest, and infrastructures utilities. Learning, generative, and simulation techniques play a critical role in building, maintaining, and updating these interconnected layers. Together, the Mobility AI Agents and Networks enable (near) real-time and offline prediction, decision-making, planning, optimization, and simulation, supporting a wide range of smart mobility applications.

This talk will elaborate on key modules required to develop the multi-layer multi-resolution MDT and the technical challenges ensuring model scalability and adaptability and maintaining computational efficiency. Additionally, practical applications of the MDT framework in transportation system will be discussed. Through these insights, the talk will demonstrate how MDTs enhance the responsiveness, efficiency, and sustainability of urban transportation networks.

3 - Leveraging Affordable Cav Edge Devices to Assist Digital Twin Modeling

Hao Zhou, University of South Florida, Tampa, FL, United States, Shengming Yuan

The widespread adoption of digital twin (DT) technology in transportation is currently constrained by its reliance on expensive, dedicated roadside sensors and communication infrastructure. This research addresses this critical gap by leveraging the untapped potential of increasingly prevalent in-vehicle sensors such as ADAS-equipped cars and user dash-cams, to offload infrastructure costs and enrich DT models. Our work bridges on-vehicle Cooperative Driving Automation (CDA) edge capabilities with sophisticated DT modeling through a framework for comprehensive data acquisition from vehicle CAN bus and external cameras. A cornerstone of our approach is the utilization of low-cost communication strategies—specifically next-generation Wi-Fi (Wi-Fi 6/7) and existing cellular networks—which obviate the need for substantial new infrastructure investments, complemented by the resilient QUIC protocol and WebP image compression. We employ Generative AI for intelligent data post-processing tailored to DT modeling standards. Critically, to compensate for the potential scarcity of dedicated edge CDA devices, we demonstrate that vision transformers can reconstruct comprehensive road scenes for DT modeling from vehicle-derived visual data, mitigating concerns about the scarcity of CDA edge deployment. This integrated strategy, by transforming vehicles into primary data contributors empowered by AI and cost-effective communication, significantly lowers the entry barrier, enabling scalable and accessible DT deployment.

Building A Level 4 A408

Data-Driven Operations

Invited Session

Applied Probability Society

Chair: Yueyang Liu, Rice University, Houston, United States

Co-Chair: Chao Qin, Stanford University, Palo Alto, CA, United States

1 - On Information Design with Spillovers

Yifan Guo, Stanford University, Stanford, CA, United States, Ozan Candogan, Haifeng Xu

An information designer chooses which experiments to assign to agents in a directed network, where agents also observe spillovers from others' experiments. We study optimal information design under different spillover modes (local vs. global) and under lossy transmission. In the global case, when each agent follows at most one other, the optimal structure is tractable; but if some follow more than one, the problem becomes NP-hard, even with simple communication technologies. Local spillovers show a different pattern: the problem remains tractable if agents follow only few others and communication is simple, but any deviation leads to intractability. Finally, we apply our framework to supply chains, where a retailer reveals demand information to affect upstream investment. By exploiting payoff structure, we obtain tractable algorithms in richer settings and highlight how different spillover types shape the retailer's payoff.

2 - Variance Aware Thompson Sampling for Expediting A/B/N Testing

Shuangning Li, University of Chicago, Chicago, IL, United States

In many experimental settings, the goal is to compare a baseline (control arm) with multiple variations (treatment arms) and maximize the probability of identifying at least one treatment that outperforms the control under a fixed sample size. The standard approach involves A/B/n testing, where experimental units are randomly assigned to the control or one of the treatment groups, followed by statistical testing (e.g., t-tests) to assess significance.

We focus on scenarios where units arrive in batches and the inference procedure—batchwise t-tests followed by aggregation—is fixed, often due to managerial or regulatory constraints. While the inference method must remain unchanged, allocation probabilities across arms can be adaptively adjusted before each batch, framing this as an optimal experimental design problem.

To this end, we develop a variance aware Thompson Sampling method. Unlike standard Thompson Sampling, our approach prioritizes treatment arms with both high expected reward and low variance, and allocates more samples to the control arm to reduce variance in comparisons. Compared to uniform randomization, this method avoids wasting samples on unpromising arms and expedite the process of identifying superior treatments under the fixed inference framework.

3 - New Relative Value Iteration Algorithms for the Ergodic Risk-Sensitive Control of Markov Chains

Nicola Sassone, Department of Computational Applied Mathematics and Operations Research, Rice University, Houston, TX, United States, Sumith Anugu, Guodong Pang

In this paper, we propose new Jacobi-like and Gauss-Seidel-like relative value iteration (RVI) algorithms for the ergodic risk-sensitive control (ERSC) problem of a controlled discrete-time Markov chain (DTMC) on discrete state space and establish their convergence. With finite state space, whenever the DTMC is irreducible and recurrent under every stationary Markov control policy, we prove that the iterates of our algorithms converge geometrically. The proof requires establishing a local contraction property, and also a local Lipschitz continuity property of the fixed point of the risk-sensitive Bellman-like operator. To tackle the challenges associated with the multiplicative nature of the operator, we employ the well-known entropy variational formula, which re-casts the operator and its fixed point equation in an additive form, albeit with an additional optimization problem over a corresponding set of probability vectors. In the case of countable state space, we propose an implementing procedure by properly truncating the problem to have finite state space. Under either uniform stability or a near-monotonicity condition, we show that as the truncation size grows indefinitely, the iterate values of our algorithms converge to the value function and the optimal ERSC cost. Finally, we implement our algorithms on two examples to demonstrate the performances of our proposed RVI algorithms: maximizing the exit rate from a finite domain (on a graph) and a single-server queue of finite capacity in the case of finite state space, and also a single-server queue of infinite capacity with abandonment in the case of countable state space.

4 - Calibration in Heavy-Tailed Machine Learning: a Statistical Perspective

Wenhao Yang, Stanford University, Stanford, CA, United States, Jose Blanchet, Peter Glynn, Aleksandar Mijatovic

Heavy-tailed noise has gained significant attention in modern machine learning due to its impact on generalization performance in stochastic training algorithms, especially stochastic gradient descent (SGD). While empirical evidence suggests that heavy-tailed noise can enhance optimization dynamics and improve model generalization, it also poses fundamental challenges for theoretical analysis and statistical inference.

In this talk, I will present a statistical perspective on the role of heavy-tailed noise in SGD, focusing on two key aspects. First, I will discuss the asymptotic properties of SGD under heavy-tailed noise, highlighting key differences from classical light-tailed theory. I will then introduce a principled approach to statistical inference for SGD-based estimators, enabling uncertainty quantification despite the presence of heavy tails. These results provide new insights into the calibration of learning algorithms under non-standard conditions, bridging the gap between optimization and statistical inference. I will conclude by discussing the implications of these findings for practical machine learning applications, highlighting open questions and future research directions in the intersection of optimization, statistical inference, and robustness in heavy-tailed settings. This talk is based on joint works with Jose Blanchet, Peter Glynn and Aleksandar Mijatović.

5 - Managing Hidden Risk in Operations: Safety and Resilience

Feng Zhu, MIT, Cambridge, MA, United States, David Simchi-Levi

This talk is about understanding and managing hidden risk in various operational decision-making environments that bear a sequential manner.

Our first focus is managing tail risk in online learning, with applications in revenue management, clinical trials, and financial investment. We give a detailed characterization of regret distribution and demonstrates how managing regret tail risk leads to extra benefits on policy robustness. In Part I, we design policies that enjoy both optimal regret expectation and light-tailed regret distribution. In Part II, we study the optimal trade-off between expectation and tail risk for regret distribution.

Notably, we find that our policy design coincides with what was adopted in AlphaGo MCTS, providing high-level insights to the success of their engineered solution in complex decision-making environments.

Our second focus is managing disruption risk in supply chains. We introduce a new supply chain resilience framework that accommodates the impact of uncertain Time-To-Recover (TTR) on risk detection, response coordination, and system recovery across general supply chains. We propose a new Risk Exposure Index for pre-disruption risk detection, characterize the price of TTR uncertainty during the intra-disruption stage via a tight theoretical analysis, and include post-disruption system recovery by considering Time-To-Recover-Inventory (TTRI). An extensive numerical study supplements our analytical findings and provides new managerial insights.

Life as a Ph.D. Student

Panel Session

Minority Issues Forum

Co-Chair: Meen-Sung Kim, Georgia Institute of Technology, Atlanta, United States

Co-Chair: Valentina Castaneda-Torres, Georgia Institute of Technology, 251 10th street NW, Atlanta, GA, 31308, United States

1 - Moderator Panelist

Meen-Sung Kim, Georgia Tech, Atlanta, GA, United States

The journey of pursuing a Ph.D. can be exciting, frustrating, rewarding, and exhausting, often all at once. In this panel, current Ph.D. students will share their personal stories: what led them to pursue a Ph.D., the challenges they've faced, and the lessons they've learned along the way. We'll talk about what it's really like to be a Ph.D. student—beyond the research papers and deadlines. Whether you're thinking about grad school or already in the middle of your program, we invite you to join us for an open, honest, and supportive conversation about navigating life as a Ph.D. student.

TSL Dissertation Award and TS Journal Paper of the Year Awards

Award Session

Transportation Science and Logistics (TSL)

Chair: Hai Wang, Singapore Management University, Singapore, Singapore

1 - Intro to the TSL Dissertation Award

Hai Wang, Singapore Management University, Singapore, Singapore

This award is the oldest and most prestigious honor for doctoral dissertations in the transportation science and logistics area.

2 - Machine Learning for Sequential Decisions in Logistics

Fabian Akkerman, University of Twente, Enschede, Netherlands

This presentation will be given by a winner of a TSL award.

3 - Analytics for Better Urban Cycling-

Bo Lin, University of Toronto, Toronto, ON, Canada

This presentation will be given by a winner of a TSL award.

4 - Combinatorial Optimization-Enriched Machine Learning to Solve the Dynamic Vehicle Routing Problem with TIME Windows

Kai Jungel, Technical University of Munich, Munich, Germany, Axel Parmentier, Leo Baty, Maximilian Schiffer, Patrick Klein

This presentation will be given by a winner of a TSL award.

5 - Electric Vehicle Scheduling in Public Transit with Capacitated Charging Station

Rolf van Lieshout, Eindhoven University of Technology, Eindhoven, Netherlands, Marelou H de Vos, Twan Dollevoet

This paper considers the scheduling of electric vehicles in a public transit system. Our main innovation is that we take into account that charging stations have limited capacity, while also considering partial charging. To solve the problem, we expand a connection-based network in order to track the state of charge of vehicles and model recharging actions. We then formulate the electric vehicle scheduling problem as a path-based binary program, whose linear relaxation we solve using column generation. We find integer feasible solutions using two heuristics: price-and-branch and a diving heuristic, including acceleration strategies. We test the approach using data from the concession Gooi en Vechtstreek in the Netherlands, containing up to 816 trips. The diving heuristic outperforms the other heuristic and solves the entire concession within seven hours of computation time with an optimality gap of less than 3%.

1 - A Dynamic Replanning Strategy for Disruption-Aware Truck and Drone Deliveries**Mehmet Kurt, Auburn University, Auburn, AL, United States**

This study explores the potential effects of stochastic disruptions, such as adverse weather and unexpected events, on the well-known Flying Sidekick Traveling Salesman Problem (FSTSP). This work introduces the first FSTSP extension that incorporates dynamic recourse planning for disruption, addressing both total and rolling disruptions. We use a dynamic re-planning strategy, where we update the entire solution based on Bayesian updates to the expected start time and duration of the disruption each time a vehicle reaches a customer location, with additional re-planning when the disruption starts and ends. This approach accounts for the stochastic nature of both disruption start times and durations with assumptions of probability distributions of these and conditioning on the current time. We follow an iterative process: we generate the initial plan, determine the next decision epoch, move to the next closest node, roll the planning horizon forward, and replan for the entire remaining day from that point—continuing this cycle until the end of the day or until a disruption is encountered and a disruption replan is executed. The mathematical model is implemented to evaluate the mitigating effect of recourse actions, with computational experiments and a comparative analysis of rolling and total disruptions. A heuristic approach is developed to handle large-scale instances. Overall, this study highlights the importance of considering disruptions in truck-and-drone delivery planning. Through a dynamic update approach that incorporates stochastic disruption details, it demonstrates how real-time adjustments can improve the efficiency and resilience of last-mile delivery operations.

2 - Target-Driven Initial Tour Construction for the Traveling Salesman Problem with Drone**Jae Hyeok Lee, KAIST, Daejeon, Korea, Republic of, Minwoo Kim, Kiyoung Um, Jinkyoo Park, Changhyun Kwon**

This research challenges a fundamental assumption in the Traveling Salesman Problem with Drone (TSP-D) solution methodologies that optimal TSP tours provide the most effective foundation for high-quality TSP-D solutions. The TSP-D involves a truck and drone collaboratively serving customers while minimizing completion time. It represents a class of problems for coordinating heterogeneous autonomous agents in logistics. Current approaches typically generate a near-optimal TSP tour and then apply dynamic programming-based partitioning to determine drone operations. Through systematic investigation, we demonstrate that this approach often yields suboptimal results. Our comparative analysis reveals that tours with specific structural characteristics—particularly configurations with pronounced angular regions—consistently produce superior TSP-D solutions despite having higher TSP costs. These structures enable more efficient drone utilization by strategically positioning launch and recovery points. Building on this insight, we develop a reinforcement learning framework that directly optimizes initial tours for TSP-D performance rather than TSP optimality. The model formulates tour construction as a sequential decision process where rewards derive from the quality of resulting TSP-D solutions after exact partitioning. Our experiments demonstrate that RL-generated tours significantly outperform those derived from optimal TSP tours when evaluated as TSP-D solutions. This work reveals a methodological blind spot in sequential optimization approaches that extend beyond TSP-D to other multi-stage problems. By reconceptualizing the initial tour generation process to target downstream performance objectives directly, we achieve substantial improvements in solution quality without increasing computational complexity. We advance the state-of-the-art truck-drone routing optimization and establish a framework for target-driven construction heuristics in complex optimization problems.

3 - Two-Echelon Collaborative Delivery Through Truck-Drone Synergy**Linxuan Shi, The George Washington University, Washington, DC, United States**

Emerging drone technologies have driven interest in last-mile delivery, offering advantages such as flexibility, fast delivery, low cost, and a reduced carbon footprint. However, drone-based delivery services face constraints, including short delivery range and limited carrying capacity, which have led logistics carriers to explore hybrid truck-drone collaboration. This study evaluates the efficiency of a hybrid delivery paradigm in which a truck travels along major arterials while multiple drones sidekick within a designated strip area alongside the truck's trajectory to perform final package deliveries. We model this problem using continuous approximations and estimate two critical system performance metrics—truck traversal time and energy consumption—through a capacitated queuing model. Theoretical analysis and numerical results indicate that system performance is highly sensitive to the way that the truck and drones coordinate, particularly the drones' serviced strip width and the speed synergy between the two modes. Findings also suggest that truck-drone collaboration outperforms a truck-only delivery mode in both efficiency metrics, with performance improving as more drones are deployed.

4 - The Generalized Driver-Aide Problem: Enhancing The Role of The Aide in Urban Last-Mile Delivery**Mengting Chao, University of Maryland-College Park, College Park, MD, United States**

The dramatic growth in package delivery volume in recent years has presented significant challenges for last-mile delivery, especially in urban areas. We introduce the Generalized Driver-Aide Problem (GDAP), where an aide can assist the driver in two modes: (i) “Jumper” mode: The aide works with the driver to expedite the delivery at a stop, and (ii) “Helper” mode: The aide is dropped off by the truck to serve multiple stops independently while the driver serves other stops and picks up the aide later. This generalized helper mode allows the aide to move between multiple stops independently, a unique feature in dense urban settings. We must determine both the delivery route and the most effective way to use the aide to minimize the total delivery time. Our primary managerial question involves exploring the benefits of the aide's independent movement in urban last-mile delivery. We develop exact approaches to solve the GDAP. First, we provide a compact MIP formulation, which can be solved directly by off-the-shelf solvers. We then develop an IP formulation with exponentially many variables and constraints. Built on this formulation, we propose a sophisticated branch-cut-and-price approach with several algorithmic enhancements. We conduct a case study involving New York City, based on real-world data and the established literature. Comparing to the traditional truck-driver delivery without the aide, the GDAP leads to significant improvements in delivery efficiency, cost reduction, environmental sustainability, and mitigation of parking-related issues.

5 - Incentive-Compatible Mechanism for Integrated Bike Rebalancing and Local Store Deliveries**Nastaran Tork, University of Minnesota, Minneapolis, MN, United States, Alireza Khani**

This study proposes an incentive-compatible framework that enlists regular bike sharing users to perform either station rebalancing or last-mile deliveries within a single, daytime platform. Users disclose walking and biking tolerances, receive bundled task offers generated by a binary optimization model, and bid for their preferred task in a reverse second-price auction. Payoffs reflect a weighted task value that blends inventory impact with an early-delivery bonus. A two-hour simulation with 2017 Nice Ride Minnesota data confirms the framework's practicality. Assuming a 95% participation rate, users assigned to rebalancing tasks walked only 8% less than usual while biking 38% less. Every assigned delivery met its deadline, and the redistribution of bikes noticeably narrowed the gap between under- and over-stocked stations. Budget analysis shows that adjusting the weights of the task value factors strongly influences which tasks receive funding and, consequently, the system's overall benefit. These findings suggest that crowdsourced daytime rebalancing, paired with on-bike deliveries, can relieve fleet imbalances and help to cut vehicle miles with minimal user burden.

Recent Advance in Theory and Applications of Facility Location

Invited Session

Location Analysis

Chair: Alan Murray, University of California at Santa Barbara, Santa Barbara, CA, United States

1 - Modified Sets of Closest Assignment Constraints for R-Hub Median Interdiction Problems**Saikat Mukherjee, Indian Institute of Technology Delhi, New Delhi, India, Prasanna Ramamoorthy**

Interdiction of hubs shows vulnerability within a hub network explaining how unanticipated occurrences or attacks can affect the network. Routing of flows can be possible through surviving hubs in post-interdiction situations. This study includes closest assignment constraints, which ensure allocation of non-hub nodes to the nearest hub nodes. In this study, hub median interdiction problem is modeled as bilevel optimization problem. These assignment constraints can be used to reformulate bilevel model into single level. We propose several alternate modified sets of closest assignment constraints. We analyze those constraints and present dominance relations among them. Experiment Results indicate that the effectiveness of constraints can create a tighter model which reduces computational complexity.

2 - A Bilevel Optimization Framework for Strategic Deployment of Survivor Geolocation Systems and Rescue Teams in Post-Disaster Operations

Jose Walteros, University at Buffalo, Buffalo, NY, United States, Angelo Joseph Soto Vergel, Diana Ramirez-Rios, Juan Borrero

The prompt collection of accurate information about potential survivor locations in the aftermath of a disaster is critical for the success of search and rescue operations. Traditional methods rely on teams combing through affected areas for signs of survivors. However, limitations on data availability, resources, and personnel can severely restrict the effectiveness of these efforts. Recent technological advancements have enabled the strategic deployment of remote sensors in affected areas, providing an effective tool for identifying signs of survivors before rescue missions are launched. The data collected by these sensors can significantly enhance the situational awareness of rescue planners, allowing them to guide rescue teams toward regions with potentially high survivor densities, thereby improving the likelihood of successful outcomes. This presentation introduces a bilevel stochastic optimization model with recourse that addresses the joint problem of placing sensor probes and deploying rescue teams. In the first level, the model selects candidate zones for deploying a set of geolocated probes equipped with various sensors (e.g., heat, sound, motion), subject to a predefined budget. These decisions rely solely on prior probabilities of the survivors' locations, inferred from pre-disaster indicators, hazard exposure risks, and socio-demographic markers. These factors serve as a general indicator of the potential presence of survivors and their level of endangerment. In the second level, the model determines the areas the teams will traverse, using the partial information collected from the deployed probes. The overarching objective of the model is to maximize the expected number of survivors that can be rescued.

3 - Dispersed and Compact Locational Siting

Alan Murray, University of California at Santa Barbara, Santa Barbara, CA, United States

The selection of areas for activity has long been of interest in location modeling. Such an area may represent a residential development, industrial processing plant, storage site, nature preserve, harvest activity and/or mitigation region, among others. Many important spatial features are often necessary or desired, including compactness and dispersion. This paper reviews approaches to accomplish these goals and introduces linear formulations to address associated needs.

1 - Counter-Interdiction via Finite-Adaptability

Ningji Wei, Texas Tech University, Lubbock, TX, United States, Zolykha Rezaei

Interdiction games are Stackelberg games in which the attacker acts as the leader, selecting an optimal disruption plan, while the defender, as the follower, responds only after observing the attacker's actions. This sequential structure places the defender at a strategic disadvantage, as any fixed or predefined response can potentially be anticipated and neutralized by the attacker. This project shifts the focus to the defender's perspective by introducing the concept of a counter-interdiction game, where the defender is equipped with a contingent response plan that adapts after observing the attacker's decision. We develop several solution methods for this problem, supported by analytical performance guarantees. Beyond interdiction, the proposed methodologies contribute to a broader framework for robust finite-adaptability optimization, enabling robust defense strategies not only against adversarial attacks but also under general uncertainty.

2 - A Robust Bilevel Network Interdiction Problem with Applications in Human Trafficking Disruption

Daniel Lopes da Silva, Clemson University, Clemson, SC, United States, Thomas Sharkey, Yongjia Song

We introduce a robust bilevel network interdiction problem inspired by applications in human trafficking disruption. In this problem, the follower, who operates the network, solves a minimum cost flow problem. The leader, who interdicts the network, minimizes the total flow on the arcs from a special set in the follower's minimum cost flow solution. The problem includes data uncertainty as the leader does not know the follower's operational cost vector. The follower has complete knowledge about its own parameters and therefore makes decisions in a "wait-and-see" manner. We present a solution approach to the optimistic version of the problem and discuss interesting observations.

3 - Mixed-Integer Programming Models for Solving Semi-Cooperative Attack Graph Problems

Phanuel Allaissem Beremadji, University of Arkansas, Fayetteville, AR, United States

In this work, we focus on the Semi-Cooperative Attack Graph Problems (SCAGP), where we aim to optimize attack strategies in interdependent networks. In our problems, network information such as the number of nodes or states, the number of arcs or exploits, is known and shared among attackers. Additionally, attackers, with their parameters and utilizing their resources, collaborate to compromise the network. We proposed mixed-integer programming (MIP) models and a Lagrangian-based decomposition model to analyze and solve the problem. The decomposition method uses a relaxed MIP as a starting point and iteratively adds valid cuts to the relaxed MIP whenever a constraint is violated. We compare the computational results of the two models on various instances with different parameters, including the size of the networks, the number of attackers, the budget, and the cost of completing exploits. For future works, we may consider alternative objective functions, including minimizing the maximum lateness or weighted total tardiness.

The SCAGP model can be applied to various domains, including defense strategies for interdependent infrastructures, wireless sensor network security, and the spread of disinformation over social networks. By considering cooperative attack scenarios, our models contribute to a more comprehensive understanding of attack dynamics and optimization in real-world settings.

4 - Mixed Integer Programming Model for Robust Multi-Commodity Flow Scheduling Problems

Md Sazid Rahman, University of Arkansas, Fayetteville, AR, United States, Robert Curry

In this presentation, we study variant of a network flow maximization problem called the Multi-Commodity Maximum Value Dynamic Flow Problem (MC-MVDFF). In this problem, we maximize the value of the multi-commodity network flow schedule on a dynamic network, where an amount of residing minimum flow of a commodity acquires value on each node at the end of a time period. We assume flows traverse the network during each time period and reside at nodes between periods. We solve a mixed-integer programming (MIP) formulation for the problem considering uncertainty on the unit cost of flow and minimum amount required to acquire value for a commodity at a node. Moreover, we robustify the MC-MVDFF model (R-MC-MVDFF) with uncertainty and add two sets of constraints to the robust model for practicality: 1) we consider a set of permanent commodities for which if we acquire value once at a node for some time period, then we acquire value for that commodity and at that node for every subsequent time periods; 2) we consider a set of prerequisite commodities for each commodity at a node and add the corresponding precedence constraint for the relationship. We consider a Constraint and Column Generation (CCG) method for solving the MIP R-MC-MVDFF by decomposing the model into path-finding subproblems and a main problem maximizing value over the worst case. We investigate the efficiency of our solution methods through rigorous computational results.

Building B Level 2 B202

Advanced Optimization for Mixed Integer Programming

Invited Session

Computing Society

Chair: Mikhail Bragin, Southern California Edison, Marina del Rey, CA, United States

1 - Lp Sampling for Improved Milp Analysis and Solution**John Chinneck, Carleton University, Ottawa, ON, Canada**

A new heuristic that generates and solves random LPs derived from a given MILP can be helpful in two situations. (1) If the MILP is infeasible, it helps to find a minimal set of integer restrictions (IRs) causing infeasibility. (2) If the MILP is feasible, it can help find an initial MILP-feasible or near-feasible solution. In case (1) most solvers do not attempt to isolate a minimal set of IRs because it takes a very long time, though this information is useful to the analyst. Doing so can also greatly speed up the isolation of the entire infeasibility (including linear constraints and variable bounds). The heuristic treats all variables as continuous and solves several LPs with varying objective function coefficients for the nominally integer variables. This is often surprisingly useful in quickly reducing the original model in case (1) and quickly providing a MILP-feasible or near-feasible solution in case (2). Experimental results are provided

2 - Learning to Tune Parameters in Multi-Period Blending Problem**Asha Ramanujam, Purdue University, West Lafayette, IN, United States, Dimitri Papageorgiou, Can Li**

The multi-period blending problem, also known as the multi-period pooling problem, involves blending streams in blenders to obtain products across different time periods. Optimizing the blending system involves solving an NP-hard non-convex mixed integer quadratically constrained problem (MIQCP). Large-scale versions of these MIQCPs can be very difficult to solve to provable optimality and even for high-quality primal solutions. In this talk, we introduce a novel, scalable method that involves tuning parameters in a low-fidelity approximation of the MIQCP so that it can achieve similar performance as the high-fidelity full-space MIQCP.

3 - Acceleration of Level Adjustment for the Polyak Stepsize: Applications to Mixed Integer Programming and Machine Learning**Mikhail Bragin, Southern California Edison, Marina del Rey, CA, United States**

The Polyak stepsize has been widely used for convex problems. However, the stepsize requires a generally unknown optimal value. To guarantee convergence, we develop a novel level adjustment approach to successively estimate the optimal value with provable convergence. This is achieved by developing a decision-based procedure through a novel easy-to-solve "Polyak Stepsize Violation Detector" (PSVD) linear constraint satisfaction problem. Once a violation is detected, a tighter level value is obtained. Furthermore, because subgradients may be computationally costly, we develop an approximate subgradient method. Through a series of empirical tests of convex functions with diverse characteristics, we illustrate the practical advantages of our approach as compared to existing methods. For Mixed-Integer Programming (MIP) problems, our integration of Lagrangian Relaxation with the Polyak stepsize demonstrates significant efficiency gains, optimizing Lagrangian dual problems in operations research, power systems, transportation, and manufacturing sectors leading to speedups of 2-3 orders of magnitude as compared to standard MIP methods.

4 - Screening Cut Generation for Sparse Ridge Regression**Guanyi Wang, National University of Singapore, Singapore, Singapore**

Sparse ridge regression is widely utilized in modern data analysis and machine learning. However, computing globally optimal solutions for sparse ridge regression is challenging, particularly when samples are arbitrarily given or generated under weak modeling assumptions. This paper proposes a novel cut-generation method, Screening Cut Generation (SCG), to eliminate non-optimal solutions for arbitrarily given samples. In contrast to recent safe variable screening approaches, SCG offers superior screening capability by identifying whether a specific $\{\pm 1\}$ combination of multiple features (binaries) lies in the set of optimal solutions. This identification is based on a convex relaxation solution rather than directly solving the original sparse ridge regression. Hence, the cuts generated by SCG can be applied in the pre-processing step of branch-and-bound and its variants to construct safe outer approximations of the optimal solution set. Numerical experiments are reported to validate the theoretical results and demonstrate the efficiency of SCG, particularly in hard real instances and synthetic instances with high dimensions, low ridge regularization parameters, or challenging modeling assumptions.

5 - Distributed Quantum Computing for Fast Restoration of Distribution Networks with Grid-Forming Ibrs**Peng Zhang, Stony Brook University, New York, NY, United States**

We will present a distributed quantum computing (DQC) framework for scalable restoration of distribution networks with grid-forming IBRs. By decomposing the global restoration problem into independent spatial subproblems, the DQC restoration framework enables parallel execution on heterogeneous quantum resources and significantly accelerates restoration decision-making, leading to reduced load loss and improved system reliability. A quantum restoration formulation that incorporates droop constraints of grid-forming IBRs is introduced to maintain frequency and voltage security throughout the restoration process. To manage the increasing model complexity from temporal decision variables, the time-series MILP models of spatial subproblems are further decomposed into smaller temporal subproblems, facilitating scalable implementation on NISQ devices. A compact and lossless transformation from MILP to QUBO is designed through a set of encoding, scaling, and tuning techniques. This minimizes the number of required qubits while preserving solution fidelity, allowing for efficient mapping of service restoration problems onto today's quantum annealers and gate-based devices.

6 - Quantum Subspace Decomposition for Large-Scale Power Grid Analysis**Yifan Zhou, Stony Brook University, Stony Brook, NY, United States**

Quantum computing holds immense potential for resolving computationally intractable problems, which ignites hope for a "quantum leap" in power grid computing. However, developing scalable quantum algorithms for power grid analysis remains challenging, due to difficulties in designing practically implementable quantum circuits and maintaining robustness under varying grid conditions and quantum noise.

This talk will present our recent work on advancing large-scale, quantum-enabled power grid analysis using Quantum Krylov Subspace (QKS) methods. The core idea is to project high-dimensional power grid models onto a lower-dimensional quantum subspace through a series of computationally manageable quantum circuits and small-scale classical problems. This approach allows solving large-scale problems while avoiding the need for complex, high-depth circuits (e.g., HHL) or heuristic variational optimization techniques. It will offer a practical and scalable path toward quantum-enhanced power grid computation for systems with tens of thousands of buses on near-term quantum devices.

Building B Level 2 B203

Algorithms for Grid Integration of AI

Invited Session

ENRE: Electricity

Chair: Vladimir Dvorkin, University of Michigan, Ann Arbor, MI, United States

1 - Toward Energy-Optimal AI Systems**Mosharaf Chowdhury, University of Michigan, Ann Arbor, Ann Arbor, MI, United States**

Generative AI adoption and its energy consumption are skyrocketing. For instance, training GPT-3, a precursor to ChatGPT, consumed an estimated 1.3 GWh of electricity in 2020. By 2022, Amazon trained a large language model (LLM) that consumed 11.9 GWh, enough to power over a thousand U.S. households for a year. AI inference consumes even more energy, because a model trained once serves millions. This surge has broad implications. First, energy-intensive AI workloads inflate carbon offsetting costs for entities with Net Zero commitments. Second, power delivery is now the gating factor toward building new AI supercomputers. Finally, this hinders

deploying AI services in places without high-capacity electricity grids, leading to inequitable access to AI services. In this talk, I will introduce the ML Energy Initiative, our effort to understand AI's energy consumption and build a sustainable future by curtailing AI's runaway energy demands. I will introduce tools to precisely measure AI's energy consumption and findings from using them on open-weights models, algorithms to find and navigate the Pareto frontier of AI's energy consumption, and the tradeoff between performance and energy consumption during model training. I will also touch upon our solutions to make AI systems failure-resilient to reduce energy waste from idling. This talk is a call to arms to collaboratively build energy-optimal AI systems for a sustainable and equitable future.

2 - Learning-Augmented Competitive Algorithms for Spatiotemporal Online Allocation with Deadline Constraints

Adam Lechowicz, University of Massachusetts Amherst, Amherst, MA, MA, United States

We introduce and study spatiotemporal online allocation with deadline constraints (SOAD), a new online problem motivated by emerging challenges in sustainability and energy. In SOAD, an online player completes a workload by allocating and scheduling it on the points of a metric space (X, d) while subject to a deadline T . At each time step, a service cost function is revealed that represents the cost of servicing the workload at each point, and the player must irrevocably decide the current allocation of work to points. Whenever the player moves this allocation, they incur a movement cost defined by the distance metric $d(\cdot, \cdot)$ that captures, e.g., an overhead cost. SOAD formalizes the open problem of combining general metrics and deadline constraints in the online algorithms literature, unifying problems such as metrical task systems and online search. We propose a competitive algorithm for SOAD along with a matching lower bound establishing its optimality. Our main algorithm, ST-CLIP, is a learning-augmented algorithm that takes advantage of predictions (e.g., forecasts of relevant costs) and achieves an optimal consistency-robustness trade-off. We evaluate our proposed algorithms in a simulated case study of carbon-aware spatiotemporal workload management, an application in sustainable computing that schedules a delay-tolerant batch compute job on a distributed network of data centers. In these experiments, we show that ST-CLIP substantially improves on heuristic baseline methods.

3 - The Dynamical Profile and Impact of Large Language Model Power Consumption

Yuzhuo Li, University of Alberta, Edmonton, AB, Canada

Large language models (LLMs) have driven unprecedented investment in AI infrastructure, with multi-hundred-billion-dollar data center expansions planned over the next 3-5 years. However, the unique dynamical power consumption profile of LLMs poses significant challenges for power grid integration and reliability. Unlike traditional loads, AI infrastructure exhibits ultra-low inertia, sharp power surges and dips, and substantial peak-to-idle power ratios spanning from hundreds of watts to gigawatts. These transient dynamics create never-before-seen grid integration challenges. This work examines the scale and characteristics of LLM power consumption, analyzing transient behavior across various operational scenarios to characterize the complex patterns of AI workload dynamics. We develop preliminary mathematical frameworks to capture key aspects of this behavior and assess their multifaceted impact on existing power grids. Our analysis reveals critical reliability and resilience concerns that emerge from the disruptive nature of AI loads, including rapid power fluctuations that challenge traditional grid stability mechanisms. The findings highlight the urgent need for interdisciplinary approaches combining machine learning expertise with power systems engineering to address these integration challenges. As AI technologies continue evolving rapidly, characterizing and understanding their dynamical power profiles becomes essential for sustainable infrastructure development. This research provides foundational insights for developing algorithms and strategies for effective grid integration of AI, offering a starting point for researchers and practitioners working at the intersection of artificial intelligence and power systems.

4 - Carbon-Aware Computing for Data Centers with Probabilistic Performance Guarantees

Sophie Hall, ETH Zürich, Zürich, Switzerland, Francesco Micheli, Giuseppe Belgioioso, Ana Radovanovic, Florian Dörfler

Data centers are significant contributors to carbon emissions and can strain power systems due to their high electricity consumption. To mitigate this impact and to participate in demand response programs, cloud computing companies strive to balance and optimize operations across their global fleets by making strategic decisions about when and where to place compute jobs for execution. In this work, we introduce a load shaping scheme which reacts to time-varying grid signals by leveraging both temporal and spatial flexibility of compute jobs to provide risk-aware management guidelines and job placement with provable performance guarantees based on distributionally robust optimization. Our approach divides the problem into two key components: (i) day-ahead planning, which generates an optimal scheduling strategy based on historical load data, and (ii) real-time job placement and (time) scheduling, which dynamically tracks the optimal strategy generated in (i). Our optimal scheduling strategy allows for incorporation of grid constraints such as power limits and ramping constraints. Further, we use a stochastic model to handle demand response events which ensures job completion requirements still hold in expectation. We validate our method in simulation using normalized load profiles from randomly selected Google clusters, using real carbon load signals, and incorporating ramping limits. We demonstrate significant reductions in carbon cost and peak power with our approach compared to myopic greedy policies, while maintaining computational efficiency and abiding by system and grid constraints.

5 - Carbon-Intelligent Compute Management Leveraging Temporal and Spatial Flexibility for Enhanced Emission Reduction

Utkarsh Shah, Google, Inc, Seattle, WA, United States, Bokan Chen, Ana Radovanovic

The carbon dioxide emitted per kilowatt-hour on an electricity grid varies based on the time of day and significantly by location due to different power generation methods. Google employs a Carbon-Intelligent Compute Management system that leverages temporal flexibility to decrease carbon emissions from electricity consumption by adjusting the timing of adaptable workloads. Expanding on this, this work introduces geographical relocation of these workloads, adding spatial flexibility. The practicality of this relocation depends on factors like data dependencies, network availability, and regulations. A spatial flexibility classifier (SFC) evaluates a job's spatial flexibility, which then informs both offline demand forecasting and online real-time cluster selection systems. Offline elements, including day-ahead spatial demand prediction, carbon intensity forecasting, and a risk-aware optimization model, produce virtual capacity curves (VCCs) for Google's data centers. These VCCs control capacity distribution across different clusters and times, ensuring the daily completion of all flexible workloads across the entire fleet with high reliability. Google's operational data shows that VCCs, in conjunction with the SFC, effectively manage cluster capacity by shifting flexible workload execution to locations and times with lower carbon intensity when a cluster's energy supply has a high carbon footprint.

1 - Modernizing Expansion Planning and Probabilistic Resource Adequacy Modeling for Spatial Reliability: Metrics and Machine Learning Feedback

Satender Gunwal, University of Illinois Chicago, CHICAGO, IL, United States, Selva Nadarajah, Todd Levin

Generation and Transmission Expansion Planning (GTEP) is essential for ensuring adequate investments in electricity supply and transmission to meet growing demand, evolving system needs, and changing technology costs. Traditional GTEP models typically focus on system-wide cost minimization and reliability via deterministic optimization. Subsequently, Probabilistic Resource Adequacy Models (PRAM) simulate operational reliability of the resulting system. However, improvements in traditional system-wide reliability metrics do not guarantee spatial reliability—consistent electricity supply across different regions—leading to critical spatial disparities. Existing approaches to spatial reliability often result in computationally intractable stochastic models or rely on ad hoc integrations between GTEP and PRAM, highlighting structural limitations. As ratepayers ultimately fund network expansions, addressing spatial disparities is essential to improve societal outcomes, build public trust, streamline permitting, and support policy objectives. Increased renewable intermittency further amplifies these challenges, necessitating modernized planning approaches.

This paper proposes the use of economic fairness metrics based on unserved energy to assess and improve spatial reliability, particularly benefiting underserved regions and vulnerable consumers. Using the county-level ERCOT network, we demonstrate that traditional GTEP models achieve aggregate reliability improvements yet fail

spatially. We then introduce a machine learning-based feedback mechanism that links GTEP and PRAM efficiently through MIP-representable random feature mapping with rectified linear unit (ReLU) activation. This approach offers computational efficiency and interpretability without disruptive software infrastructure changes. We illustrate the benefits of this feedback mechanism using Garver 6-bus test system to demonstrate its effectiveness and interpretability.

2 - Decomposition Algorithms for Stochastic Capacity Expansion with Endogenous Adequacy Targets

Marilena Zampara, National Technical University of Athens, Athens, Greece, Daniel Felipe Avila, Anthony Papavasiliou

The scope of this work is to test alternative algorithmic schemes for addressing a large stochastic capacity expansion problem with specific constraints on expected energy not served. The challenge lies in decoupling scenario-specific variables, which are originally bundled by adequacy constraints, so that scenario-specific problems can be solved in parallel. The examined schemes include Benders' decomposition, the projected subgradient method, the level method, and Dantzig-Wolfe decomposition. The schemes are tested in a pan-European capacity expansion model, considering 35 scenarios for climatic conditions.

3 - Reliability Impacts of Energy Storage Profitability Considerations in Electricity Market Models

Mark Noll, Northwestern University, Evanston, IL, United States, David Morton

Many options exist for scheduling energy storage in resource adequacy models. An approach that has become widespread in recent work has been to establish a day-ahead schedule for storage and then assume that operations in real-time do not deviate from the day-ahead schedule except in extreme circumstances, such as to replace operating reserves or prevent load shedding. In reality, storage units that operate in restructured electricity markets have more leverage to choose their schedules in the real-time market than assumed by this modeling paradigm. From a reliability perspective, there is a concern that storage units may prematurely deplete their stored energy when RT prices are high but storage is not needed to prevent a loss-of-load event, leaving the storage fleet without stored energy to prevent a loss of load event later in the day.

In this work, we explore the conditions under which storage units, operating with imperfect foresight in day-ahead and real-time markets, may choose to deviate from their day-ahead schedule in real-time operations. To represent the perspective of storage units operating under uncertainty, we solve a sequence of hourly rolling horizon stochastic optimization models that maximize risk-adjusted future profits for the storage unit, accounting for the storage unit's day-ahead schedule and forecasts of real-time prices in the future. We aim to clarify the conditions under which profit-seeking storage behavior may reduce availability during reliability events. These insights can inform future RA modeling assumptions and operational practices in modern electricity markets.

4 - Resilient Power System Design Against Climate Hazards

Brayam Valqui Ordenez, EPRI, Palo Alto, CA, United States, Miguel Ortega-Vazquez, Eknath Vittal

Developed and applied a resilient generation expansion model to the Alliant bulk power system to evaluate long-term investment strategies under climate-driven extreme events. Resilience is embedded into capacity the planning model by explicitly representing extreme event risks, which are multifaceted and uncertain. The planning approach optimizes expansion and hardening investments by treating events as multicriteria stress tests that prevent unacceptable unmet demand and damage outcomes, while costs are optimized over ordinary operating conditions. Each event contains multiple hazards that disrupt operations, damage assets (as a function of their vulnerabilities), and increase demand. System resilience is measured using a load loss tolerance (LLT) metric, which defines the allowable level of unmet demand during extreme conditions. Resiliency is guaranteed by sensitivity analysis across a range of LLT values while also enforcing a net-zero emissions target by 2050. Results show that lower LLT thresholds shift the optimal portfolio toward firm, dispatchable, carbon-free capacity, with increased investment in technologies such as hydrogen-enabled RICE and gas peaker RICE, as well as targeted hardening of thermal generators through winterization and chiller technologies. These shifts reflect the dual objectives of enhancing resilience and achieving long-term decarbonization. At the same time, investments in wind, solar, and storage decline moderately as the system prioritizes clean dispatchable capacity under stress conditions. These changes result in total investment and operational cost increases ranging from 0.2% (LLT0.3) to 11% (LLT0) relative to the baseline scenario (i.e., full loss during stress scenarios).

Improving Mine Planning and the Minerals Supply Chain, and mitigating wildfires

Invited Session

ENRE: Natural Resources

Chair: Alexandra Newman, Colorado School of Mines, Golden, CO, United States

1 - Shortest Path: Ramp Optimization in Open Pit Mining

Felix Ayaburi, Colorado School of Mines, Lakewood, CO, United States, Bingshen Lu

Haul Road Optimization in Open-Pit Mining aims to reduce fuel consumption and operational costs by improving ramp design for large haul trucks. Traditional methods rely on heuristics and often overlook the impact of terrain, slope, and truck constraints on efficiency.

We model the mine surface as a 3D graph where nodes are connected based on distance and slope thresholds. Using Python and NetworkX, we implement the A* algorithm with edge weights that penalize steep gradients and tight turns, accounting for vehicle size, turn radius, and ramp width. This allows us to generate realistic, fuel-efficient haul routes for Komatsu 930Es and Hitachi EH5000ACs.

Current results demonstrate optimized surface paths that reduce travel distance and fuel usage. Future work will extend to subsurface planning, evaluating the trade-offs between material removal and long-term haulage efficiency.

2 - Multi-Objective Optimization of Drill Pattern Design for Increased Ore Recovery and Reduced Impact Mining

Ozan Perincek, Rio Tinto, Perth, Australia, Ryan Loxton, Sarang Kulkarni, Daniel Arthur

Drill and blast processes aim to optimize the fragmentation of rocks for efficient hauling and crushing. Due to environmental considerations and scarcity of resources, the focus is now shifting towards reducing carbon emissions and minimizing ore loss. Blasting is more energy efficient than crushing for breaking rocks and controlling rock movement during blasting can reduce dilution and improve ore recovery. Existing work has used initiation timing design to blast ore away from waste but does not consider the optimal placement of drill holes to enhance ore-waste separation. Poor drill hole placement may lead to suboptimal fragmentation with large rock sizes, resulting in energy-intensive downstream processing. We consider the multi-objective optimization of energy consumption and ore-waste separation by determining drill hole locations and explosive product in each hole. In a two-phase approach, first, we minimize the total mining energy by achieving optimal fragmentation. Second, using this energy as a bound, we re-optimize the positions of the drill holes to maximize ore recovery. The algorithm uses a heuristic approach to deal with complexities such as nonlinearity and an unknown number of drill holes to provide decision support for the fragmentation vs ore recovery tradeoff. Additionally, the model considers ease of navigation within the drill pattern for drills and explosive delivery trucks. Simulations of six blast scenarios using data from a Rio Tinto mine site in Western Australia indicate that trading off fragmentation and optimizing hole position with specialized initiation timing can recover between 3% to 9% more ore than just utilizing timing.

3 - Optimizing Haul Trucks Maintenance Scheduling in Open Pit Mines: Case Study on Modelling Around Complexity

Fredrick Ehichioya, Imperial Oil, Calgary, AB, Canada, Bart Maciszewski, Siddhesh Inamdar, Jose Santiago Rodriguez Osorio, Anuraj Grewal, Christine Vilijoen, Amber McKay, Ervin Balleza, Andrew Milne, Jacob Olafsen, Cathy Giang, Hussam Mansour, Pujit Jetley, Brendan Cumming

We present a case study of building a model to schedule maintenance for heavy haul trucks in an oil sands mine and its refinement over time to expand scope and meet business needs. In this problem the trucks require periodic preventive maintenance based on operating hours and in addition to break-in work. There is a need to schedule

close to due dates while grouping activities to minimize the number of truck visits to the shop. Activities need to be performed on compatible bays and need to respect the amount of available resources. We decompose the problem into a grouping and detailed scheduling stage and solve it using constraint programming with a rolling horizon approach. We show how we adapted the model to cover diverse mine equipment fleets and complex business requirements through separation of data processing, mathematical modelling, and integration of machine learning.

4 - Use of Gen AI to Improve Mining Workforce Efficiency

Hannah Zhao, Imperial Oil Limited, Calgary, AB, Canada, Amy Liang, Fredrick Ehichioya, Trevor Lew, Anuraj Grewal, Bryan Kan

At UDA, we are building applications that leverage generative AI to enhance the efficiency of troubleshooting processes in mining operations. By providing real-time information retrieval, the AI system optimizes troubleshooting workflows and improves worker productivity.

1 - Carbon-Aware Electric Load Shifting and Its True Impact on Emissions

Line Roald, University of Wisconsin - Madison, Madison, WI, United States, Joseph Gorka, Wenqian Jiang, Noah Rhodes

An increasing number of individuals, companies and organizations are interested in computing and minimizing the carbon emissions associated with their real-time electricity consumption. To achieve this, they require a carbon signal, i.e. a metric that defines the real-time carbon intensity of their electricity supply. Unfortunately, in a grid with multiple generation sources and multiple consumers, there are multiple ways to define this signal, each of which has a distinct set of properties and method of calculation. It remains unclear which signal best quantifies the carbon footprint of electricity. This paper seeks to inform the discussion about which carbon signal is better or more suitable for two important use cases, namely carbon-informed load shifting and carbon accounting. We do this by developing a new software package `ElectricityEmissions.jl`, that computes several established and newly proposed carbon emission metrics for standard electric grid test cases. We also demonstrate how the package can be used to investigate the effects of using these metrics to guide load shifting. Our results affirm previous research, which showed that the choice of carbon emission metric has significant impact on shifting results and associated carbon emission reductions. In addition, we demonstrate the impact of load shifting on both the consumers that perform the shifting and consumers that do not. Disconcertingly, we observe that shifting according to common metrics such as average carbon emissions can reduce the amount of emissions allocated to the consumer doing the shifting, while increasing the total emissions of the power system.

2 - Impacts of Varying Approaches to Clean Electricity Accounting

Pieter Gagnon, Colorado School of Mines, Golden, CO, United States

What is the system-level impact of different approaches for REC-based clean electricity accounting? Does lower participation in a program necessarily mean the program has lower impact, or can more stringent accounting approaches drive greater change with lower participation? In this study we use a capacity expansion model to explore the interaction of electricity and environmental markets in the US, and how design attributes like spatial and temporal matching can influence the impact of an accounting approach. This work explores a range of assumptions about the elasticity of consumer's demand for clean power, to characterize how changes in the stringency of clean electricity accounting approaches can influence their ultimate impact.

3 - Market Signals and Incentives Aren't Sufficient: the Case for Supply-Chain Modeling for Grid Expansion

Boyu Yao, Johns Hopkins University, Baltimore, MD, United States, Yury Dvorkin

Until recently, grid expansion planning has assumed that asset deployment responds coherently to both electricity and environmental market signals, while overlooking upstream constraints. In practice, however, supply chain dynamics—such as material shortages, spatial constraints, and deployment timelines—distort the link between market signals and actual deployment. To be effective, grid expansion must account for supply chain and infrastructure realities to ensure that market signals translate into achievable outcomes. The first part of this talk evaluates renewable capacity expansion under realistic constraints, including material availability, land use limits, and lead times. Results show that meeting clean energy targets with renewables alone may be infeasible once rising demand from electric vehicles, data centers, and other sectors are taken into account. The second part extends the analysis to the demand for solid-state electronics—including inverters, converters, and transformers—which are critical for both integrating renewables and replacing aging grid infrastructure. Projections of future infrastructure needs highlight substantial material and component requirements, alongside growing cross-sectoral competition for these resources. Together, these findings point to a structural misalignment between market-based incentives and the physical feasibility of grid asset deployment.

4 - Perspectives on the System Impacts of Alternative Clean Electricity Procurement Strategies Using An Investment Planning Framework

Dharik Mallapragada, Tandon School of Engineering, New York University, Brooklyn, NY, United States, Zhetao Chen, Christoph Graf

Quantifying CO₂ emissions from electricity use is increasingly important for economy-wide decarbonization, as consumers seek to evaluate the impact of actions like electrification and clean power procurement. This has led to growing interest in granular emissions accounting methods that capture dynamics of grid operations to inform consumer procurement strategies. Two emerging approaches include: (i) *Emissions matching*, where consumers aim to minimize their grid emissions, measured using location- and time-specific marginal emissions factors; and (ii) *Temporal matching*, which aligns electricity use with low-carbon generation (e.g., hourly) as a proxy for emissions tracking.

Capacity expansion models (CEM) have proven valuable in systematically assessing the long-term cost and emissions implications of consumer-driven clean electricity procurement under varying grid and technology scenarios. We review CEM-based assessments of clean electricity procurement to highlight areas for further research: (a) impacts of inter-annual weather variability on matching performance; (b) interactions—competitive or coordinated—among consumers with differing strategies, load shapes, and locations; and (c) the influence of diverse consumer preferences around risk and clean energy procurement.

We then explore a decentralized framework for long-term investment planning in the power sector with the potential to address some of the above gaps around consumer coordination and preferences. This framework employs the Alternating Direction Method of Multipliers (ADMM) to compute equilibria in a non-cooperative game among heterogeneous consumers. Using a Texas case study, we compare the outcomes and scalability of the ADMM-based framework with those using a traditional CEM, offering insights into the trade-offs between centralized and decentralized methods.

5 - Optimizing the Economics and Reliability of 24/7 Power Purchase Agreements with Hybrid Energy Resources

Zhi Zhou, Argonne National Laboratory, Lemont, IL, United States, Dongwei Zhao

Power Purchase Agreements (PPAs) are increasingly favored by large energy consumers, such as AI data centers, for procuring reliable and cost-effective electricity. While traditional PPAs typically operate on a pay-as-produced basis with annual supply-demand balancing, emerging needs are driving a shift toward hourly matching of

supply and demand. Achieving this level of granularity requires the integration of flexible energy resources, such as hydropower and energy storage, to complement variable renewables like wind and solar. These hybrid configurations form the foundation of 24/7 flexible energy PPAs.

This study presents an integrated optimization framework for designing 24/7 PPA from the PPA provider's perspective. The provider procures hybrid resources and designs PPAs to meet users' hourly electricity demand. The framework incorporates both dispatchable resources (e.g. reservoir hydropower) and non-dispatchable renewables to enhance overall supply flexibility and economics. It jointly optimizes resource procurement, operational scheduling, and PPA pricing, with the objective of minimizing contract costs or maximizing provider profit. Simulation results demonstrate the critical role of flexible resources in enabling cost-effective 24/7 energy delivery. Sensitivity analyses further illustrate how hydropower flexibility and pricing mechanisms affect revenue distribution and cost allocation among providers, users, and the broader energy system.

Applications of OR/IE Models in Health and Public Policy

Invited Session

Health Applications Society

Chair: Suyanpeng Zhang, Northwestern University, Evanston, IL, United States

1 - Improving Cystic Fibrosis Screening Through a Novel Testing Design

Hussein El Hajj, Santa Clara University, Santa Clara, CA, United States, Douglas Bish, Ebru Bish

Newborn screening (NBS) plays a key role in detecting life-threatening genetic disorders, with cystic fibrosis (CF) being a prominent example. With over 1,000 CF-causing variant types, a genetic test that can detect enough variant types for sufficient screening accuracy is expensive and capacity-constrained. Consequently, in the US, the first tier of testing uses an inexpensive biochemical test that measures immunoreactive trypsinogen (IRT) levels, which are often elevated in CF cases. Genetic testing is reserved for a small fraction of newborns with elevated IRT levels, based on an IRT threshold. However, setting an optimal threshold presents challenges, particularly due to variations in IRT levels and CF prevalence among different racial and ethnic groups. As a result, the current practice of using a single IRT threshold for all newborns is not necessarily the most efficient or equitable strategy.

We introduce a novel screening design, integrating an inexpensive small-panel genetic test (DNA) before the IRT test. This strategy customizes IRT thresholds based on the number of variants detected by the small-panel DNA. This design leads to novel optimization problems, including variant type selection for the small-panel DNA and IRT threshold customization. We establish key structural properties of optimal IRT thresholds and develop Pareto frontiers that inform decision-makers about the efficiency versus equity trade-off, considering a minimax type equity measure. The case study, utilizing CF NBS data from the states of New York and California, demonstrates the potential efficiency and equity gains of this novel approach compared to current practice and race-based benchmarks.

2 - Examining the Unintended Impacts of Disruptions to the Illicit Drug Market on Violent Crime and Overdose Death

Regan Richardson, North Carolina State University, Raleigh, NC, United States, Laura Mora, Osman Ozaltin, Maria Mayorga, Brad Ray, Amang Sukasih, Phillip Lee, Lance Couzens, Nur Kaynar

The use of illicit substances remains an ongoing and widespread part of society, with the illegal drug market estimated to be 1% of the total global trade. The true scale of this market is unknown because it is an illicit underground trade that is poorly understood, dynamic, and complex. While there have been trends towards decriminalization or legalization of marijuana in the United States, the overarching policy and strategy has been consistently been to allocate large amounts of resources to law enforcement agencies to disrupt and dismantle illicit distribution networks. Therefore, the purpose of this project is to utilize national integrated data to develop an understanding of the impact of law enforcement disruptions to the illicit drug supply on both public health (e.g. overdoses) and public safety (e.g. violent crime) outcomes. In the present study, we utilize multivariate granger-causality to investigate the relationships between police drug seizures and violent crime rates, and between police drug seizures and overdose death rates using data from the National Incident Reporting System (NIBRS) and the National Center for Health Statistics Mortality Data from CDC WONDER.

3 - Multi-Modal Machine Learning for Breast Cancer Recurrence Prediction

Jiahao Shao, The University of Tennessee Knoxville, Knoxville, TN, United States, Xudong Wang, John Bell, Xueping Li, Bing Yao

Breast cancer recurrence, a leading cause of long-term mortality among survivors, requires timely and accurate risk assessment to guide follow-up care and treatment planning. Traditional predictive models, often limited to either structured or unstructured data alone, struggle to capture the full clinical context. This study examines the impact of integrating multi-modal clinical data, including treatment records, pathology reports, and clinician notes, on recurrence prediction. Large language models (LLMs) are used to extract key prognostic variables such as tumor grade and hormone receptor status from free-text pathology narratives. These outputs are cross-validated against rule-based extractions to improve consistency and build trust in downstream modeling. We also benchmark performance against commonly used feature sets from prior breast cancer studies to assess the added value of multi-modal integration. Single-source and multi-modal inputs are evaluated across a range of machine learning models, including both interpretable and black-box approaches. Results show that multi-modal integration consistently improves predictive accuracy compared to single-modal methods.

4 - Deepsynergy: Fusing Hybrid Optimization and Shallow-Deep Ensembles for Enhanced Breast Cancer Survival Analysis

Nikoo Ebrahimi, Binghamton University (SUNY), Binghamton, NY, United States, Sadaf Tabatabaee, Sreenath Chalil Madathil, Mohammad Khasawneh

Accurate breast cancer survival prediction is a critical clinical challenge in machine learning. We introduce a deep learning framework, called DeepSynergy, that combines shallow network insights and hybrid optimization to predict breast cancer survivability using the SEER breast cancer dataset. This dataset provides comprehensive, de-identified records of female patients diagnosed with complete follow-up through a defined cutoff period. This research incorporated six variants and three synergistic models for the base DeepSurv model to enhance training and predictive performance. The six variants include checkpointing, gradient clipping, Optuna-based hyperparameter tuning, refined best hyperparameter with AdamW optimization, stochastic gradient descent, and a hybrid optimizer combining SGD warm-up with AdamW fine-tuning. The synergistic model includes augmented deep model inputs with intermediate hidden representations, a gated-fusion ensemble using the shallow log-risk score, and a parallel dual-path architecture for multimodal representation learning. We applied inverse probability of censoring weighting (IPCW) to mitigate censoring bias and improve reliability. All models were evaluated using C-index, IBS, and time-dependent AUC at 1, 3, 5, and 10 years. The hybrid optimizer and the ensemble model demonstrated superior calibration, faster convergence in risk discrimination, and strong early-stage survivor stratification, highlighting their potential for clinical decision-making in early phases of treatment. We employed SHAP and LIME for post hoc interpretability to improve model transparency. Both methods consistently identified nodal involvement, tumor grade, and staging completeness as the most influential predictors across models. These findings underscore the potential of DeepSynergy as an explainable and deployable decision support tool in oncology.

5 - Personalized Risk Assessment and Treatment Recommendation for Substance use Disorders

Eric Pulick, University of Wisconsin - Madison, Madison, WI, United States, Yonatan Mintz

Substance use disorders (SUDs) are a widespread and growing global health concern. In the United States (US) alone, nearly fifty million people meet the diagnostic thresholds for an SUD. However, fewer than 15% of those with SUDs receive any form of treatment. Even fewer receive the type of long-term, continuing care often associated with successful recovery. Digital therapeutics platforms (e.g., an app on a mobile device) are emerging as a low-cost and low-burden way to interact with SUD patients, both to gather longitudinal data and curate resources for continuing care. In this talk, we discuss the use of personalized state space models for assessing SUD patient risk and their extension to adaptive control frameworks for personalized treatment selection. We validate these approaches using datasets built from digital therapeutics studies that followed patients with alcohol- and opioid use disorders for 3-12 months.

6 - Representing Caregiver Burden in Observational Studies: Development of the Caregiver Burden Index (Carebi)

Forough Mahpouya, University at Buffalo, Buffalo, NY, United States, Sabrina Casucci, Suzanne Sullivan, Christopher Barrick

Informal caregiving, provided by over 53 million adults in the US, often carries a significant emotional, physical, and financial toll, or caregiving burden. Unpaid caregivers manage responsibilities that significantly affect both their own well-being and their care recipients' outcomes, yet caregiver burden is rarely reflected in healthcare decision-making frameworks. Existing caregiver burden instruments, while valuable in clinical research, often lack compatibility with observational datasets regularly used in health services research and planning. This study introduces the Caregiver Burden Index (CareBI) using data from the National Study of Caregiving, that can be used to represent caregiver burden in quantitative models and research based on observational data. We will discuss our development process, relevant indicators and burden domains, and alignment of CareBI with the Zarit Burden Index, a widely used tool for prospectively assessing caregiver burden. We will also discuss how we evaluated our scale for construct validity by assessing its relationship with caregiver and care recipient outcomes, as well as sensitivity to known burden-related risk and mitigation factors. Early findings affirm the scale's utility in categorizing low-, moderate-, and high-burden caregivers and guiding resource-oriented strategies. CareBI represents a reproducible tool for embedding caregiver metrics into health operations, predictive modeling, and public policy frameworks, and provides a template for applying operations research and industrial engineering methods to psychosocial measurement challenges in aging and long-term care.

7 - Screening and Sensibility: a Societal Approach to Disease Screening for Patient with Multiple Chronic Conditions

Ali Hajjar, MBSC, King Abdullah Economic City, Saudi Arabia, Oguzhan Alagoz

Existing clinical practice guidelines tend to overlook the unique requirements of patients with multiple chronic conditions (MCC) by primarily focusing on the management of individual diseases. This inadequately personalized approach leads to adverse events and places a financial strain on the healthcare system, particularly in countries with large or growing populations. To address this issue, our study utilizes a stochastic modeling approach to optimize disease screening decisions while considering financial and resource limitations from a broader societal perspective.

8 - Data-Driven Frameworks for Quantifying Relationships Between Diseases

Hari Balasubramanian, University of Massachusetts, Amherst, Amherst, MA, United States

The prevalence of multiple chronic diseases among patients is increasing globally. Systematic approaches to identify relationships between diseases are essential for: (1) prevention, diagnosis, and treatment planning; and (2) epidemiological insights on how different organs and body systems might be linked together. In this talk, we discuss examples from the literature, methodologies, and datasets that can help identify associations between diseases.

1 - Water Network Design and Operation: Leveraging Linear Approximations

Sourabh Kumar Choudhary, Georgia Institute of Technology, Atlanta, GA, United States, Santanu Dey, Nick Sahinidis

This study concerns the optimal design and operation of produced water and urban water networks. We address a key challenge in solving these: the representation of frictional pressure changes across network nodes using nonlinear constraints, typically modeled by the Hazen-Williams equation. For the optimization of produced water networks, we analytically show the effectiveness of using a standard piecewise linear approximation to generate near-optimal solutions for the original problem for a general network. Computational results with real-world problems confirm the success of this approach. However, in the context of urban water network design problems, we recognize the limitations of a direct piecewise-linear approximation and propose an alternative solution. In particular, we develop a general-purpose primal heuristic to handle MINLPs with nonlinearities in continuous variables.

2 - Computing Clusters in Networks Using Continuous Cubic Formulations

Ashwini Ravindran, Texas A&M University, College Station, TX, United States, Sergiy Butenko

We study alternative continuous cubic formulations for a class of fundamental cluster-detection problems in networks, including the maximum clique, s-defective clique, s-plex, and the independent union of cliques problems. These combinatorial problems, central to graph theory and network analysis, have wide-ranging applications in social network analysis, bioinformatics, and communication systems. The considered formulations capture the structural properties of these discrete problems while enabling their treatment within a continuous optimization framework. Each problem is modeled as the maximization of a degree-three multi-linear polynomial objective over a polyhedral feasible set defined by either the standard simplex or unit hypercube.

These continuous models provide new perspectives for theoretical analysis and algorithmic development. In particular, we derive analytical bounds that offer insight into the quality of feasible solutions and can be used to guide solution refinement. Additionally, we leverage the structure of the cubic formulations to design local and global solution methods based on existing nonlinear optimization solvers.

To assess the practical utility of our approach, we conduct a comprehensive computational study on standard benchmark instances. We compare the performance of multiple solvers in terms of solution quality, computational efficiency, and scalability. Our numerical results demonstrate the effectiveness of the proposed formulations in yielding high-quality solutions and suggest that continuous polynomial models can serve as a powerful alternative to traditional discrete or integer programming techniques for cluster detection in complex networks.

3 - New Methods for Computing the Value Function of Mixed Integer Programs

Siva Ramani, Rice University, Houston, TX, United States, Tu Nguyen, Andrew Schaefer

In mixed integer programming (MIP), the MIP value function (MIPVF) is the optimal value of MIP parametrized by its right-hand side. MIPVF has been leveraged in various algorithmic approaches to solve stochastic MIPs and special cases of bilevel optimization problems and inverse MIPs. We develop a new procedure that exploits the structure of MIPVF in conjunction with results from polyhedral theory and MIP duality to efficiently compute the MIPVF. Our algorithm is scalable and we demonstrate how to leverage our procedure along with other decomposition methods to solve a wide array of problems such as large-scale stochastic MIPs, inverse MIPs, and bilevel programs.

4 - Bilevel Risk-Averse Routing and Resource Allocation for Urban Air Mobility

Haoyun Deng, Georgia Institute of Technology, Atlanta, GA, United States, Weijun Xie

Urban air mobility (UAM) provides a promising solution for alleviating ground traffic congestion and achieving zero direct aviation emissions. The successful and reliable implementation of UAM requires careful coordination between regulatory authorities, such as the Federal Aviation Administration (FAA), and airline operators, particularly in uncertain conditions of passenger demand and airspace capacity. In this paper, we introduce a bilevel risk-averse optimization framework that integrates airline routing decisions with FAA capacity management and delay assignment at critical airspace bottlenecks. To address the computational complexity of this integrated routing and resource allocation problem, we propose and evaluate both heuristic and exact optimization methods. Numerical experiments demonstrate the effectiveness of the proposed approaches and provide valuable insights for stakeholders seeking efficient, equitable, and robust UAM operations in uncertain environments.

1 - Conservative OR Risk-Taking? Objective Selection for Fair Allocation and Routing in Nonprofits**Haiqing Gao, Northwestern University, Evanston, IL, United States, Seyed Iravani, Dawson Ren, Sean Sinclair**

We investigate an online fair sequential allocation problem in which a central planner distributes a divisible resource across multiple locations under demand uncertainty. Motivated by real-world applications, we integrate routing decisions into the planner's problem and formulate dynamic programs (DPs) that jointly optimize allocation and visitation order for two max-min fairness objectives: $\{ \text{ex-post} \}$ and $\{ \text{forward} \}$. Leveraging these formulations, we derive structural insights into the optimal policy. Our main contributions are twofold: First, we show that for any fixed visitation order, the optimal allocation policy follows a $\{ \text{threshold structure} \}$ governed by an $\{ \text{equating property} \}$: locations with sufficiently low demand are fully satisfied, while the remainder receive proportional allocations. Second, we characterize the optimal routing policy and prove that, under mild conditions, it is optimal to visit locations in decreasing order of their demand's coefficient of variation (CV). We complement our theoretical results with a numerical study using real-world data from a food pantry network. Our experiments compare various fairness objectives across multiple fairness metrics, highlighting how each approach navigates the equity-efficiency trade-off. These results offer practical insights into the policy implications of adopting different fairness criteria in dynamic resource allocation.

2 - Coordinator or Active Participant? the Food Banks Role in Ad-Hoc Food Rescue Operations**Irem Sengul Orgut, Loyola University Chicago, Chicago, IL, United States, Shabnam Salehi, Lauren Davis, Emmett Lodree**

In the United States, food banks distribute donated food to individuals and families in need through networks of partner agencies, aiming to ensure fair distribution, minimize waste, and reduce costs. While most donations are received in bulk through scheduled agreements with major donors, food rescue efforts redirect surplus food from smaller-volume donors through ad-hoc, opportunistic donations. These efforts differ from traditional operations in both timing and logistics. This study examines how food banks can best support food rescue activities while balancing geographic equity, effectiveness, and efficiency. We focus on two operational models: a centralized approach, in which the food bank both coordinates and directly participates in rescue efforts, and a decentralized model, where the food bank acts solely as a coordinator and partner agencies handle collection and distribution. Through an extensive numerical study motivated by the real-world operations of our food bank partner, we find that conventional supply chain wisdom favoring centralization does not always apply. When agencies have sufficient storage and rescue capacity, decentralized coordination is more advantageous. In contrast, when agency capacity is low, food bank participation (centralization) leads to better outcomes. We also evaluate food waste impacts and find that centralized models benefit centrally located urban areas, while decentralized systems show no advantage based on proximity to the food bank.

3 - Online Fair Division: Towards Ex-Post Constant Mms Guarantees**Parnian Shahkar, University of California, Irvine, Irvine, CA, United States, Pooja Kulkarni, Ruta Mehta**

We investigate the problem of fairly allocating m indivisible items among n sequentially arriving agents with additive valuations, under the sought-after fairness notion of maximin share (MMS). We first observe a strong impossibility: without appropriate knowledge about the valuation functions of the incoming agents, no online algorithm can ensure any non-trivial MMS approximation, even when there are only two agents. Motivated by this impossibility, we introduce **OnlineKTypeFD** (online k -type fair division), a model that balances theoretical tractability with real-world applicability. In this model, each arriving agent belongs to one of k types, with all agents of a given type sharing the same known valuation function. We do not constrain k to be a constant. Upon arrival, an agent reveals her type, receives an irrevocable allocation, and departs. We study the ex-post MMS guarantees of online algorithms under two arrival models:

1- *Adversarial arrivals*: In this model, an adversary determines the type of each arriving agent. We design a $1/k$ -MMS competitive algorithm and complement it with a lower bound, ruling out any $\Omega(1/\sqrt{k})$ -MMS-competitive algorithm, even for binary valuations.

2- *Stochastic arrivals*: In this model, the type of each arriving agent is independently drawn from an underlying, possibly unknown distribution. Unlike the adversarial setting where the dependence on k is unavoidable, we surprisingly show that in the stochastic setting, an asymptotic, arbitrarily close-to- $1/2$ -MMS competitive guarantee is achievable under mild distributional assumptions.

Our results extend naturally to a learning-augmented framework as the competitive ratios of our algorithms degrade gracefully with multiplicative prediction errors.

4 - Forward-Backward Contention Resolution Schemes For Fair Rationing**Will Ma, Columbia Business School, New York, NY, United States, Calum MacRury, Clifford Stein**

We use contention resolution schemes (CRS) to derive algorithms for the fair rationing of a single resource when agents have stochastic demands. We aim to provide ex-ante guarantees on the level of service provided to each agent, who may measure service in different ways (Type-I, II, or III), calling for CRS under different feasibility constraints (rank-1 matroid or knapsack). We are particularly interested in two-order CRS where the agents are equally likely to arrive in a known forward order or its reverse, which is motivated by online rationing at food banks.

In particular, we derive a two-order CRS for rank-1 matroids with guarantee $1/(1+e^{-1/2}) \approx 0.622$, which we prove is tight. This improves upon the $1/2$ guarantee that is best-possible under a single order (Alaei, SIAM J. Comput. 2014), while achieving separation with the $1-1/e \approx 0.632$ guarantee that is possible for random-order CRS (Lee and Singla, ESA 2018). Because CRS guarantees imply prophet inequalities, this also beats the two-order prophet inequality with ratio $(\sqrt{5}-1)/2 \approx 0.618$ from (Arsenis, SODA 2021), which was tight for single-threshold policies. Rank-1 matroids suffice to provide guarantees under Type-II or III service, but Type-I service requires knapsack. Accordingly, we derive a two-order CRS for knapsack with guarantee $1/3$, improving upon the $1/(3+e^{-2}) \approx 0.319$ guarantee that is best-possible under a single order (Jiang et al., SODA 2022). To our knowledge, $1/3$ provides the best-known guarantee for knapsack CRS even in the offline setting. Finally, we provide an upper bound of $1/(2+e^{-1}) \approx 0.422$ for two-order knapsack CRS.

Stochastic and Noisy Algorithms for Continuous Optimization

Invited Session

OPT: Nonlinear Optimization

Chair: Frank E. Curtis, Lehigh University, Bethlehem, PA, United States

1 - Negative Curvature Methods with High Probability Complexity Bounds for Stochastic Nonconvex Optimization**Wanping Dong, University of Michigan, Ann Arbor, MI, United States, Albert Berahas, Raghu Bollapragada**

We consider two-step negative curvature methods for solving nonlinear nonconvex unconstrained optimization problems, where function, gradient, and Hessian evaluations are provided by oracles. We establish second-order convergence results under two types of oracle models. First, we analyze two-step methods with constant step sizes under deterministic inexact oracles, deriving deterministic second-order guarantees and iteration complexity bounds under reasonable assumptions. Building on this, we extend the analysis to probabilistic oracles, where the function, gradient, and Hessian estimates satisfy accuracy conditions with high probability. The algorithm we propose incorporates an early stopping mechanism to ensure sufficient progress at each step and a step search strategy based on Armijo-type conditions to dynamically

adjust step sizes for both steps. These strategies enable high-probability second-order convergence guarantees and iteration complexity bounds. Numerical results on machine learning problems demonstrate the efficiency of the proposed method in practice.

2 - A Sequential Cubic Optimization Method with Second-Order Complexity Guarantees for Equality Constrained Optimization

Nikolaos Dimou, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

We develop a new method for equality constrained optimization based on a sequential cubic optimization framework. Each iteration utilizes a step decomposition based on the Jacobian of the constraints into a normal and a tangential component, the latter of which is found by solving a subproblem involving cubic regularization. The method incorporates second order correction steps as necessary to ensure global convergence to second order stationary points, as well as local quadratic convergence. In addition, we show that the algorithm is the first to obtain worst-case complexity guarantees on the order of $\epsilon^{-3/2}$ for the gradient of the Lagrangian, ϵ^{-3} in terms of second order stationarity, and ϵ^{-1} in terms of the constraint violation. These complexity guarantees are the best known results of any method for this class of problems.

3 - Progressive Sampling for Equality Constrained Optimization with Expectation Constraints

Lingjun Guo, Lehigh University, Bethlehem, PA, United States, Frank Curtis, Daniel Robinson

We consider the problem to minimize a smooth objective function subject to equality constraints. In particular, we are motivated by the setting of constrained supervised machine learning where the aim is to minimize an empirical loss function subject to constraints defined by an expectation or large finite sum. In this context, utilizing exact constraint gradient information requires a pass over all samples in the dataset, which can be prohibitively expensive when the number of samples is large. Thus, we propose a progressive sampling strategy that initially solves a subproblem whose constraints only use a small subset of the full samples, then progressively increases the size of the subset while solving each subproblem approximately until the solution reaches the desired accuracy. Numerical simulations demonstrate that our method can outperform an approach that solves the original problem directly when performance is measured by the number of sample constraint gradients requires to obtain a solution of comparable quality.

4 - Adaptive Stochastic Gradient Tracking Methods for Decentralized Optimization

Wei Wang, The University of Texas at Austin, Austin, TX, United States, Albert Berahas, Raghu Bollapragada

In decentralized optimization, multiple nodes in a network collectively solve an optimization problem over a global objective function. Gradient tracking methods have emerged as a popular approach in this subfield, as they offer both strong theoretical guarantees and robust empirical performance. In these methods, the complexity of the two operational steps—computing local gradients and communicating between nodes—must be balanced for various large-scale stochastic optimization applications. In this work, we adopt an adaptive sampling method using a well-known norm test within a stochastic version of a flexible, unified gradient tracking framework. The proposed framework unifies existing gradient tracking methods while dynamically controlling sampling selection for local gradient approximation at each node and employing a randomized communication scheme. We establish convergence guarantees in expectation and analyze the complexity of both computation and communication. Numerical experiments on logistic regression and quadratic problems illustrate the effectiveness of the proposed framework.

5 - Active-Set Identification in Noisy and Stochastic Algorithms

Lara Zebiane, Lehigh University, Bethlehem, PA, United States, Frank E. Curtis, Daniel Robinson

We will discuss theoretical guarantees pertaining to constrained optimization problems. In particular, we will focus on noisy and stochastic methods and their ability to identify optimal active-constraint sets. A major challenge in this context is that, since the function and derivative values have error, standard techniques might fail to identify the correct active-constraint set even at a local minimizer. We will show that, even in the presence of errors, estimates can be computed that will identify the correct active-constraint set when the errors are accounted for appropriately. We also provide some numerical demonstration of our theoretical guarantees.

Data-Driven and Distributionally-Robust Optimization under Distribution Shifts

Invited Session

OPT: Optimization Under Uncertainty

Chair: Dominic Keehan, University of Auckland, Auckland, New Zealand

1 - Incorporating Unknown Trust into Decision Recommendation with Multi-Sourced Reference Information

Yanru Guo, University of Michigan, Ann Arbor, MI, United States, Ruiwei Jiang, Siqian Shen

Navigating the complexities of decision-making processes relies heavily on the ability to integrate information from multiple sources, especially in environments where uncertainty exists. In this study, we investigate a stochastic optimization problem where the probability distributions of uncertain parameters are estimated using reference information from various sources. We conduct non-parametric data fusion based on trust over different sources to construct the Wasserstein ambiguity set and formulate a distributionally robust optimization (DRO) model to minimize potential worst-case losses. In addition, we design a dynamic trust update framework and propose multiple update rules to simulate decision maker's trust variation. We demonstrate the effectiveness of our approaches using instances of preventive care allocation.

2 - Don't Look Back in Anger: Wasserstein Distributionally Robust Optimization with Nonstationary Data

Dominic Keehan, University of Auckland, Auckland, New Zealand

We study data-driven decision-making problems in which historical data is sampled from a sequence of distributions that change over time. Every consecutive distribution is shifted by at most a certain Wasserstein distance. To address this nonstationarity, we propose a distributionally robust optimization with a Wasserstein-ball based ambiguity set. At the center of this ball is a weighted empirical distribution on the historical data. By deriving a concentration inequality for weighted empiricals which explicitly incorporates the possible distribution shift, we optimize the datum weightings, and thereby maximize the probability that our ambiguity ball contains the next distribution in the sequence. When there is no distribution shift, our approach naturally recovers standard Wasserstein distributionally robust optimization. Moreover, it reveals a relationship between the order of the Wasserstein ambiguity ball and the decay profile of the optimal datum weightings. Comparison of the resulting weightings shows that simple weighting approaches like windowing and exponential smoothing are near optimal. Numerical experiments demonstrate the effectiveness of our approach.

3 - Nonstationary Distribution Estimation via Wasserstein Probability Flows

Edward Anderson, Imperial College London, Cambridge, United Kingdom, Dominic Keehan

We consider a situation in which historical observations are drawn from an underlying probability distribution which changes over time. We model changes in the distribution nonparametrically, and suppose that changes are likely to involve a small Wasserstein distance between two consecutive distributions. This leads naturally to a formulation in which we estimate the underlying series of distributions by maximizing the log likelihood of the observations with a penalty applied to the sum of the Wasserstein distances between consecutive distributions. We call this the Wasserstein Probability Flow problem, and show how it reduces to a simple network-flow problem. This can be easily solved, and we derive some properties of its optimal solutions. A range of numerical experiments in different settings show that the Wasserstein Probability Flow method for estimating distributions can be effective in practice.

4 - Ambiguity Updating Robust Architecture: Updating Ambiguity Sets with Revealed Uncertainty in Multi-Period Dro

Gar Goei Loke, Durham University Business School, Durham, United Kingdom, Wenxin Liu, Yu Zhang, Aakil Caunhye

We study the context of multi-period distributionally robust optimization, where uncertainties are revealed sequentially and the decision-maker wishes to re-solve the problem-to-go, utilizing this information to shrink the ambiguity set of distributions-to-go, while remaining consistent with the original ambiguity set. We propose a model, termed Ambiguity Updating Robust Architecture (AURA), that defines the ambiguity sets for the problems-to-go. Here, AURA does not require uncertainties to be

independent across time, or explicit characterization of the conditional distribution of the uncertainties on those at prior times. We show that the robust counterpart of AURA can be tractably computed. Under linear assumptions, AURA can be reformulated as a linear optimization model with number of decision variables and constraints that grows quadratically in time.

5 - Towards Optimal Offline Reinforcement Learning

Mengmeng Li, Ecole Polytechnique Federale de Lausanne (EPFL), Lausanne, Switzerland, Daniel Kuhn, Tobias Sutter

We study offline reinforcement learning problems with a long-run average reward objective. The state-action pairs generated by any fixed behavioral policy thus follow a Markov chain, and the empirical state-action-next-state distribution satisfies a large deviations principle. We use the rate function of this large deviations principle to construct an uncertainty set for the unknown true state-action-next-state distribution. We also construct a distribution shift transformation that maps any distribution in this uncertainty set to a state-action-next-state distribution of the Markov chain generated by a fixed evaluation policy, which may differ from the unknown behavioral policy. We prove that the worst-case average reward of the evaluation policy with respect to all distributions in the shifted uncertainty set provides, in a rigorous statistical sense, the least conservative estimator for the average reward under the unknown true distribution. This guarantee is available even if one has only access to one single trajectory of serially correlated state-action pairs. The emerging robust optimization problem can be viewed as a robust Markov decision process with a non-rectangular uncertainty set. We adapt an efficient policy gradient algorithm to solve this problem. Numerical experiments show that our methods compare favorably against state-of-the-art methods.

Network Optimization in Power System Operations and Planning

Invited Session

OPT: Network Optimization

Chair: Behnam Jabbari Marand, North Carolina State University, Raleigh, NC, 27606, United States

1 - Path-Based Valid Inequalities for Voltage Angle Differences in Optimal Transmission Switching

Behnam Jabbari Marand, North Carolina State University, Raleigh, NC, United States, Adolfo Escobedo

The switching of transmission lines can significantly enhance the economic and operational efficiency of power systems. The Direct-Current Optimal Transmission Switching (DC-OTS) problem which minimizes power generation costs through reconfiguration of the transmission network under the DC power flow model, provides a formal optimization framework for making these strategic decisions. DC-OTS is typically formulated as a mixed-integer linear program, incorporating disjunctive constraints to enforce Kirchhoff's Voltage Law (KVL) via big-\$M\$ parameters. In angle-based formulations, these parameters represent upper bounds on voltage angle differences across transmission lines; yet in practice, overly conservative (and arbitrary) bounds tend to be used. The belief is that tightening these values requires the solution of the longest path problem, which is computationally intractable. In this work, we present a more efficient and theoretically grounded alternative. To that end, we derive an extended formulation of the convex hull of a relaxation of the DC-OTS feasible region. From this formulation, we obtain strong path-based valid inequalities that tighten big-\$M\$ parameters and compare them against the cycle-based inequalities proposed by Kocuk et al. 2016. Computational experiments on standard benchmark instances show that incorporating these inequalities within a cutting-plane framework substantially improves solver performance, demonstrating their practical effectiveness for solving large-scale DC-OTS problems.

2 - Mixed Integer Programming Formulations for Optimal Power Flow

Gonzalo Gomez Abejon, Rice University, Houston, TX, United States, Illya Hicks

Optimal Power Flow in AC electrical grids is a nonconvex problem for which it can be notably difficult to obtain tight dual bounds and certify global optimality. Lower bounds are typically found by solving convex relaxations, which can only approximate the original constraints to a certain extent.

Instead, we explore mixed integer programming relaxations that approximate the nonconvex constraints by a union of n polytopes and can produce an arbitrarily small duality gap if solved exactly. We propose MILP formulations that only require $O(\log(n))$ total variables and constraints to approximate certain nonlinear constraints, an exponential reduction over previous formulations, and prove that this bound is asymptotically optimal, that is, that we can only reduce the formulation size further by a constant factor. Finally, we present some computational experiments where the performance of MIP relaxations is compared with standard convex relaxations for AC Optimal Power Flow.

3 - High-Spatial Resolution Transmission and Storage Expansion Planning for High-Renewable Power Systems: a Case Study

Kevin Wu, Georgia Institute of Technology, Atlanta, GA, United States, Rabab Haider, Pascal Van Hentenryck

The U.S. electric grid faces increasing challenges due to growing renewable energy integration and rising electricity demand. To ensure reliable and cost-effective power delivery under these conditions, long-term Transmission Expansion Planning (TEP) and energy storage deployment must be coordinated. This paper presents a scalable, high-resolution framework for joint TEP and storage planning, addressing tractability limitations that have constrained prior work to smaller or more aggregated systems.

A multiperiod power transfer distribution factor (PTDF)-based DC optimal power flow (DCOPF) formulation is developed, enabling direct modeling of storage impacts on line flows over a 24-hour horizon. To improve computational performance, flow constraints are added lazily in batches sorted by violation severity. For broader scalability across multiple representative days, Benders decomposition is employed with several convergence accelerators, including in-out stabilization and core-point perturbations.

This approach is demonstrated on a 2,000-bus synthetic Texas system under 2050 decarbonization scenarios. The results highlight the critical role of co-optimized storage and transmission in reducing congestion, improving reliability, and lowering system costs. This work offers a tractable pathway for high-resolution long-term planning in future renewable-heavy grids.

4 - Power System State Estimation by Phase Synchronization and Eigenvectors

Iven Guzel, University of Illinois Urbana-Champaign, Urbana, IL, United States, Richard Zhang

To estimate accurate voltage phasors from inaccurate voltage magnitude and complex power measurements, the standard approach is to iteratively refine a good initial guess using the Gauss-Newton method. But the nonconvexity of the estimation makes the Gauss-Newton method sensitive to its initial guess, so human intervention is needed to detect convergence to plausible but ultimately spurious estimates. This paper makes a novel connection between the angle estimation subproblem and phase synchronization to yield two key benefits: (1) an exceptionally high quality initial guess over the angles, known as a spectral initialization; (2) a correctness guarantee for the estimated angles, known as a global optimality certificate. These are formulated as sparse eigenvalue-eigenvector problems, which we efficiently compute in time comparable to a few Gauss-Newton iterations. Our experiments on the complete set of Polish, PEGASE, and RTE models show, where voltage magnitudes are already reasonably accurate, that spectral initialization provides an almost-perfect single-shot estimation of angles from moderately noisy bus power measurements (i.e. pairs of PQ measurements), whose correctness becomes guaranteed after a single Gauss-Newton iteration. For less accurate voltage magnitudes, the performance of the method degrades gracefully; even with moderate voltage magnitude errors, the estimated voltage angles remain surprisingly accurate.

5 - Stochastic Nodal Power System Capacity Expansion Planning with Siting of Large Loads

Tomas Valencia Zuluaga, Lawrence Livermore National Laboratory, San Francisco, CA, United States, Simon Pang, Jean-Paul Watson

Traditional power grid expansion planning studies assume that load growth is an exogenous parameter of the optimization model. The proliferation of datacenters supporting the so-called AI revolution, as well as industrial facilities built for direct air capture of CO₂ are challenging this view. These loads can be sited with some flexibility and are large enough to have an impact on the electricity network, even at the transmission level. In this work, we incorporate large-scale loads with flexible siting as part of the decision variables in a nodal capacity expansion planning model and implement a decomposition methodology to solve this optimization problem exploiting parallel computing. We show through some numerical testcases on realistic systems based on California and South Carolina the impact of proactive load siting on the need for transmission investments with different power flow formulations to highlight the importance of incorporating them into software planning tools.

GPU-Based Mathematical Optimization

Invited Session

OPT: Linear and Conic Optimization

Chair: Haihao Lu, MIT, Chicago, IL, 02139, United States

Co-Chair: Jinwen Yang, University of Chicago, Chicago, IL, United States

1 - Gpu-Accelerated Linear Programming and Beyond**Jinwen Yang, University of Chicago, Chicago, IL, United States**, Haihao Lu

The rapid progress in GPU computing has revolutionized many fields, yet its potential in mathematical programming, such as linear programming (LP), has only recently begun to be realized. This talk aims to provide an overview of recent advancements in GPU-based first-order methods for LP, with a particular focus on the design and development of cuPDLP. The extensions to GPU-based optimization beyond LP, including quadratic, semidefinite and conic programming, will also be discussed.

2 - Mpx: Mathematical Programming in Jax**Zedong Peng, MIT, Cambridge, MA, United States**, Haihao Lu, Jinwen Yang

We introduce MPAX (Mathematical Programming in JAX), a versatile and efficient toolbox for integrating mathematical programming into machine learning workflows. MPAX implemented the state-of-the-art first-order methods, restarted average primal-dual hybrid gradient and reflected restarted Halpern primal-dual hybrid gradient, to solve linear programming and quadratic programming problems in JAX. It provides native support for hardware accelerations along with features like batch solving, auto-differentiation, and device parallelism. Extensive numerical experiments demonstrate the advantages of MPAX over existing solvers. The solver is available at <https://github.com/MIT-Lu-Lab/MPAX>.

3 - Large-Scale Semidefinite Programming with Gpu-Accelerated Admm**Heng Yang, Harvard University, Boston, MA, United States**, Shucheng Kang, Xin Jiang, Antoine Groudiev

Large-scale semidefinite programs (SDPs) are increasingly important due to the growing use of semidefinite relaxations—particularly the Moment-SOS hierarchy—in engineering and applied sciences.

In this talk, we show that the Alternating Direction Method of Multipliers (ADMM) can serve as a powerful and broadly applicable first-order algorithm for solving large-scale SDPs.

First, we present a new theoretical result that challenges the common perception that ADMM is limited to medium-accuracy solutions. Specifically, we prove that if ADMM converges to a primal-dual solution pair satisfying strict complementarity, it achieves local linear convergence. Extensive numerical experiments on a wide variety of SDP instances support our theory and demonstrate that ADMM can reach high-accuracy solutions—even in the absence of nondegeneracy conditions.

Second, we present cuADMM, a generic GPU-accelerated ADMM-based solver for large-scale SDPs. We demonstrate its superior performance compared to existing SDP solvers, highlighting its potential for scaling semidefinite optimization to previously intractable problem sizes.

4 - Solving Large-Scale, Sparse, Constrained Nonlinear Optimization Problems on Gpus**Sungho Shin, Massachusetts Institute of Technology, Cambridge, MA, United States**, François Pacaud, Alexis Montoisson

In this talk, we delve into recent advancements in solving large-scale sparse nonlinear optimization problems on GPUs. This new approach combines three key elements: (1) the SIMD abstraction of nonlinear optimization problems, (2) the condensed-space interior point method approach, and (3) NVIDIA's recently released sparse linear solver, CUDSS. By combining these components, we provide a comprehensive nonlinear optimization solution capabilities. We present numerical experiment results showcasing over 10x speed-ups when applying this method to large-scale AC optimal power flow problems. We will conclude the discussion by examining the potential implications of these findings for the future of power system optimization and decision-making.

5 - Pdc: a Primal-Dual Large-Scale Conic Programming Solver with Gpu Enhancements**Zikai Xiong, Operations Research Center, MIT, Cambridge, MA, United States**, Zhenwei Lin, Dongdong Ge, Yinyu Ye

In this talk, we introduce the Primal-Dual Conic Programming Solver (PDCS), a large-scale conic programming solver with GPU enhancements. Problems that PDCS currently supports include linear programs, second-order cone programs, convex quadratic programs, and exponential cone programs. PDCS achieves scalability to large-scale problems by leveraging sparse matrix-vector multiplication as its core computational operation, which is both memory-efficient and well-suited for GPU acceleration. The solver is based on the restarted primal-dual hybrid gradient method but further incorporates several enhancements, including adaptive reflected Halpern restarts, adaptive step-size selection, adaptive weight adjustment, and diagonal rescaling. Additionally, PDCS employs a bijection-based method to compute projections onto rescaled cones. Furthermore, cuPDCS is a GPU implementation of PDCS and it implements customized computational schemes that utilize different levels of GPU architecture to handle cones of different types and sizes. Numerical experiments demonstrate that cuPDCS is generally more efficient than state-of-the-art commercial solvers and other first-order methods on large-scale conic program applications, including Fisher market equilibrium problems, Lasso regression, and multi-period portfolio optimization. Furthermore, cuPDCS also exhibits better scalability, efficiency, and robustness compared to other first-order methods on the conic program benchmark dataset CBLIB. These advantages are more pronounced in large-scale, lower-accuracy settings.

1 - Accelerating Airport Decarbonization Through Multi-Stage Stochastic Optimization and Vehicle-to-Grid Integration and Renewables**Benjamin Amoh, Dartmouth College, Lebanon, NH, United States**

Airports are energy-intensive infrastructures with growing pressure to decarbonize amidst rising electrification demands and sustainability mandates. This presentation introduces a comprehensive decision-support framework for optimizing airport energy transitions using a multi-stage stochastic optimization model. Our approach simultaneously addresses investment planning in renewable energy (solar and wind), battery energy storage, and electric ground support equipment (e-GSE), while accounting for deep uncertainties in weather and demand over a multi-decade horizon.

To tackle the complexity of high-dimensional temporal uncertainty, we apply k-means clustering on 49 years of hourly solar irradiance and wind speed data to construct 15 representative weather scenarios, weighted monthly using a Wasserstein distance approach. These scenarios drive our stochastic model, capturing seasonal and long-

term climate variability. We further incorporate vehicle-to-grid (V2G) strategies by modeling the battery capacities of airport-owned EV fleets—including buses, pushback tractors, and baggage loaders—while accounting for battery degradation dynamics. This enables airports to leverage existing mobile storage assets to reduce peak demand charges and support grid stability. Our model is applied to several major U.S. airports with distinct energy profiles, revealing optimal investment pathways that balance emissions reduction, cost-effectiveness, and operational reliability. Results show that integrating renewables, V2G, and robust planning techniques can yield up to 35% cost savings and 60% emission reductions compared to static strategies. This work demonstrates a scalable, data-driven framework that aligns infrastructure decarbonization with resilience and efficiency—offering actionable insights for airport authorities, energy planners, and policymakers.

2 - Optimizing Shared Micromobility Service Network Design

Vikrant Vaze, Dartmouth College, Hanover, NH, United States, Pushendra Singh

Shared micromobility systems (SMS), including bike and e-scooter sharing, support the shift toward sustainable urban mobility. However, their financial viability hinges on balancing capital investment and service reliability. Oversized fleets and stations waste resources, while shortages reduce customer satisfaction. This paper presents a mathematical and computational framework to optimize SMS design by aligning capacity decisions with customer demand. We formulate a mixed-integer non-convex optimization model to determine station locations, capacities, and micromobility and rebalancing vehicle fleet sizes. Our model integrates customer preferences via a discrete choice framework and captures key operational and rebalancing dynamics.

We develop an original spatial decomposition heuristic. It separates the overall model into station-location-specific models and couples operations at individual stations through iterative bilevel updates. Local updates are computationally less expensive, occur at a higher frequency, and improve station-specific solutions, whereas the global updates are computationally more expensive, occur at a lower frequency, and reset the errors accumulated over multiple local updates to drive the solution toward optimality.

Extensive experiments using real-world data show that our approach delivers near-optimal solutions, while reducing computational times by several orders of magnitude. This scalability enables system-wide optimization, serving up to 14% more demand, and generating 82% higher profitability, and 17% lower rebalancing costs than current practice. Ultimately, our comprehensive optimization formulation combined with our efficient solution approach provides bottomline improvement annually worth 8-40 million dollars to the system operator, enhances system accessibility to the customers, and reduces environmental footprint, resulting in a more profitable, accessible and sustainable micromobility system.

3 - Multi-Objective, Large-Scale, Stochastic Optimization for Green Energy Infrastructure to Service Conflict-Affected Regions of Africa

Lilly Yang, Dartmouth College, Hanover, NH, United States, Siqi Ke, Vikrant Vaze

Fragile states struggle with chronically low electrification rates, acute vulnerability to the effects of climate change, and heavy dependence on imported diesel that frequently which often leads to violence and conflict related to fuel transport. United Nations (UN) peacekeeping force compounds often correspond to a disproportionate share of the national electricity consumption, while adjacent communities remain largely underserved—highlighting the need to leapfrog the traditional fossil-fuel based grid development and adopt decentralized renewable solutions. This study presents a two-stage stochastic, multi-objective optimization framework for designing and operating decentralized hybrid renewable-energy systems (D-HRES) in fragile states. The model jointly optimizes upfront investment, diesel consumption, community coverage, and supply reliability. Uncertainty in renewable availability is captured through a scenario set reduced from 20 years of weather data via exact integer programming. First stage of the stochastic optimization framework determines the technology mix and installed capacities, whereas the second-stage decisions optimize hourly dispatch for each realized scenario. This multi-objective, large-scale, stochastic optimization problem is solved with an ϵ -constraints solution approach, and results are benchmarked against true optima as well as against a state-of-the-art multi-objective metaheuristic approach (called NSGA-II). Case studies across sub-Saharan Africa, supported by site-specific data from field experts, demonstrate the framework's transferability and yield actionable trade-off insights for planners and humanitarian agencies.

4 - Policy-Aligned Generative AI: a Practical Playbook for Trust in Public-Interest Systems

Varsha Shukla, Dartmouth College, Hanover, NH, United States

Public agencies and regulated enterprises are adopting generative AI, but many deployments stall on questions of safety, bias, privacy, and accountability. This talk offers a practical playbook for making generative AI policy-aligned and trustworthy in public-interest domains such as health, mobility, and energy. I translate high-level principles (fairness, transparency, human oversight, data minimization) into concrete engineering and product practices: role-based access, PHI-safe data paths, model and data provenance, evaluation plans tied to use-case risk, red-team protocols, audit logs, and clear rollback procedures.

Using a healthcare analytics copilot as a case example, I show how to combine a semantic data layer with guardrails (schema-aware text-to-SQL, codebook versioning, pre-execution checks) and with governance assets (model cards, risk registers, incident response runbooks). I then outline how the same controls generalize to mobility (service design under equity constraints) and energy (planning under uncertainty), where decisions carry real-world impact.

Attendees will leave with a checklist that links policy goals to measurable controls, what to track before launch (intended use, data lineage, evaluation criteria), during operation (drift, access, cost/safety thresholds), and after (auditability and remediation). The emphasis is on simple, repeatable mechanisms that raise trust while keeping teams productive and within budget.

1 - Informing Breast Cancer Control Policy Through Mathematical Modeling: the Cancer Intervention and Modeling Surveillance Modeling (Cisnet) Experience

Oguzhan Alagoz, University of Wisconsin-Madison, Madison, WI, United States

Breast cancer remains the most common non-skin cancer and the second leading cause of cancer-related death among women in the United States. While mammography continues to be the most effective diagnostic tool for breast cancer detection, it involves several risks, including a relatively high rate of false positives. Therefore, a careful balance of benefits and harms is essential in the design of mammography screening schedules.

This presentation focuses on the pivotal role of mathematical modeling in optimizing breast cancer screening strategies, with a particular emphasis on the University of Wisconsin Breast Cancer Simulation Model (UWBCS), a member of the National Cancer Institute's Cancer Intervention and Surveillance Modeling Network (CISNET). The UWBCS integrates extensive data sources, including SEER, BCSC, NHIS, and the clinical literature, to simulate real-world screening behaviors, tumor growth dynamics, detection mechanisms, and treatment dissemination. The model successfully replicated age-, subtype-, and stage-specific incidence, survival, and mortality patterns reported in SEER and externally validated against Wisconsin Cancer Reporting System and the UK AGE Screening Trial.

Real-world policy decisions have been directly informed by the UWBCS. Most significantly, the model was employed by the U.S. Preventive Services Task Force, alongside other CISNET models, to guide the national breast cancer screening recommendations in 2009, 2016, and 2024. In addition, it impacted the 2024 screening

guidelines by the National Comprehensive Cancer Network for women with high-risk genetic variants. The model was recently adopted by the Canadian Partnership Against Cancer.

2 - Modeling the Natural History of Ovarian Cancer

Iakovos Toumazis, The University of Texas MD Anderson Cancer Center, Houston, TX, United States, Sayaka Ishizawa, Larissa A Meyer

Background: Ovarian cancer is the second leading cause of death among all gynecologic cancers. Yet, no effective prevention program currently exists. Well-validated natural history models (NHMs) provide insights on the natural progression of diseases and can be used to assess the effectiveness of potential interventions in silico. Currently, no histology-specific NHM exist for ovarian cancer.

Methods: We developed histology-specific NHMs for the seven most common ovarian cancer subtypes using discrete-time Markov models. We calibrated histology-specific model parameters using Adaptive Simulated Annealing such that model outcomes reliably reproduced the observations from the Surveillance, Epidemiology, and End Results (SEER) program. We assessed goodness-of-fit using the weighted sum of root mean squared error (RMSE). We validated the NHMs on data from the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial (PLCO) and the United Kingdom Collaborative Trial on Ovarian Cancer Screening (UKCTOCS). Moreover, the stage distribution at diagnosis was validated on PLCO data. Differences between observations and model estimates were evaluated using the Pearson's chi-squared test.

Results: The calibrated NHM showed satisfactory goodness of fit to the SEER data, within 2% of RMSE. In model validation, none of our model estimates showed significant difference on UKCTOCS (p-value on incidence=0.399, death=0.377) or PLCO (p-value on incidence=0.207, death=0.513, stage distribution=0.498) observations.

Conclusion: The developed NHM accurately describes the histology-specific natural progression of ovarian cancer. This model could be used to assess the impact of future and emerging ovarian cancer preventive interventions, thus assisting policy makers developed effective prevention programs.

3 - Political Leadership and Contraceptive Uptake

Dwaipayan Roy, University of Virginia Darden School of Business, Charlottesville, VA, United States, Amir Karimi

In low- and middle-income countries (LMICs), government health facilities are the primary providers of contraceptives, especially for the poorest populations. In India, over 85% of the lowest-income users rely on government health facilities for contraception. However, contraceptive uptake in India remains low—almost 50 million women fall into this category, accounting for 90% of unintended pregnancies. This study examines whether publicly elected female leaders affect contraceptive uptake in India's government health facilities. Using a quasi-experimental design based on close elections in 692 districts over a decade, we find that female legislators increase the uptake of intra-uterine devices (IUDs), a long-acting reversible method. Additional analysis reveals that female legislators boost contraceptive counseling by frontline health workers, expand contraceptive awareness through mass media, and increase postpartum sterilizations. These pathways suggest that female leaders promote reproductive health (RH) in their communities more than their male peers. Our findings highlight female political leadership as a key operational lever to improve RH outcomes. With India's recent legislation to reserve one-third of assembly seats for women, similar reforms in other LMICs could help enhance contraceptive uptake. These insights also contribute to the global health operations literature by identifying female political leadership as a critical factor in improving contraceptive uptake.

4 - Examining Perinatal Regionalization in Practice: a Network Analysis of Maternal Transport in Georgia

Jingyu Li, Georgia Institute of Technology, Atlanta, GA, United States, Lauren Steimle, Stephanie Radke

Perinatal regionalization is a systems-level strategy for coordinating care to ensure pregnant people receive timely care in facilities with risk-appropriate personnel and services. Inter-facility transport of patients to risk-appropriate facilities is a critical component of regionalized systems. As regionalized systems of maternal care are recently emerging, it remains unclear how maternal transport is being operationalized in practice. Using network analysis, we constructed maternal transport network to represent maternal transport routes (network edges) among obstetric facilities (network nodes) as directional network. We characterized patients and regions that were more likely to be involved in transport, and those more likely to be transported across the state's designated perinatal regions. Network metrics were used to discern dynamics and structure of maternal transport in each perinatal region. Finally, we applied Louvain community detection algorithm to cluster obstetric facilities into communities that are observed to transport among each other most frequently. We compared these algorithm-detected communities with state's formal designated perinatal regions. We demonstrated this data-driven approach using maternal transports as indicated on 2017-2022 birth records from the state of Georgia. We identified 8 algorithm-detected communities within each of which transports were coordinated frequently. While these detected communities were largely aligned with the state's designated perinatal regions, geographical proximity between facilities and transporting within health systems tend to trump formal perinatal region designations. Redesigning the state's perinatal region to align with the observed maternal transport networks and to formalize relationships that are naturally occurring in practice could potentially improve access to risk-appropriate maternal care.

1 - Fairness-Promoting Integer Programming Approaches for Medical Resident Rotation Scheduling

Karmel Shehadeh, University of Southern California, Los Angeles, CA, United States, Shutian Li, Frank Curtis, Beth Hochman

Motivated by our collaboration with a residency program at an academic health system, we propose new integer programming (IP) approaches for the resident-to-rotation assignment problem (RRAP). We first present an IP formulation for the RRAP, which mimics the manual method for generating rotation schedules in practice and can be easily implemented and efficiently solved using off-the-shelf optimization software. However, it can lead to disparities in satisfying vacation requests among residents. To mitigate such disparities, we derive a fairness-promoting counterpart, which finds an optimal rotation schedule that maximizes the number of satisfied vacation requests and minimizes a measure of disparity in satisfying vacation requests. Then, we propose a computationally efficient Pareto Search Algorithm capable of finding the complete set of Pareto optimal solutions to the equity-promoting IP within a time that is suitable for practical implementation. In addition, we present a user-friendly tool implementing the proposed models to automate the generation of the rotation schedule. Finally, we construct diverse RRAP instances based on data from our collaborator and conduct extensive experiments to illustrate the potential practical benefits of our proposed approaches. Our results demonstrate the computational efficiency and implementability of our approaches and underscore their potential to enhance fairness in resident rotation scheduling.

2 - Enhancing Safety Signaling: Integrating Clinical Trials and Post-Marketing Adverse Event Reports

Fernanda Bravo, UCLA Anderson School of Management, Los Angeles, CA, United States, Yunliang Chen, John Silberholz

Adverse drug reactions (ADRs) are harmful side effects that can lead to emergency room visits and fatalities. While regulators like the FDA aim to detect ADRs during clinical trials before a drug reaches the market, these trials often lack the size or duration to catch rare or delayed effects. As a result, post-approval surveillance systems, such as the FDA's FAERS, play a critical role in detecting safety signals—potential indicators of harmful side effects. However, these observational systems suffer from biases due to variations in how and when patients report side effects, potentially leading to both false alarms and overlooked risks.

To improve this process, we propose a Bayesian framework that integrates data from pre-marketing clinical trials with post-marketing observational data. The method estimates and corrects biases in the observational data using patterns observed in more common ADRs, under the assumption that both common and rare ADRs are affected by similar reporting and selection biases. The proposed approach allows for more reliable hypothesis generation about drug safety issues. Through analytical

modeling and empirical testing using real clinical and FAERS data, we show that our method can significantly reduce the likelihood of false positives and missed true ADRs. Specifically, it can lower expected costs by 1-3% rel. to an alternative Bayesian approach that ignores common ADRs. For regulatory agencies, this methodology offers a practical and impactful enhancement to post-market drug safety monitoring, improving the accuracy and speed of ADR detection using already available data.

3 - Provider Payment Models for Transformative Technologies in Healthcare

Tinglong Dai, Johns Hopkins University, Baltimore, MD, United States, Elodie Adida

Transformative technologies such as robotic surgery hold promise for improving medical practice and patient outcomes. Despite this potential, their adoption in healthcare is constrained by high costs, the need for customization, and the absence of suitable payment models. This paper examines how provider payment models influence both the adoption of new technologies (downstream) and the quality of these tools (upstream).

We develop a game theoretical framework to analyze the strategic interaction between a developer—who sets the price and determines the tool's quality—and a healthcare provider, who decides on usage based on the reimbursement structure and the expected benefit from the technology. Under the current norm of no reimbursement, providers restrict usage to complex cases, resulting in limited adoption and suboptimal quality. Fee-for-service models encourage broader usage but create perverse incentives: high reimbursement rates prompt developers to reduce quality, while low rates may induce higher quality but fall short of socially optimal outcomes. We propose a hybrid model that blends fee-for-service with value-based payments, showing that effective incentive alignment hinges on using value metrics focused on the tool's quality—measured through documentable developer effort—rather than downstream outcomes. Interestingly, we find that as development costs rise, the minimum fee-for-service required to align incentives actually falls.

Our framework offers practical guidance for policymakers and payers aiming to craft reimbursement models that support the development and diffusion of high-quality technologies. By aligning incentives for developers and providers, these models can help integrate cutting-edge tools into clinical practice, enhancing both quality and access.

4 - Paving the Way for More Accessible Cancer Care in Low-Income Countries with Optimization

Abel Sapirstein, Georgia Institute of Technology, Atlanta, GA, United States, Lauren Steimle, Mathieu Dahan

Cancers are a growing cause of morbidity and mortality in low-income countries. Geographic access plays a key role in both timely diagnosis and successful treatment. In areas lacking well-developed road networks, seasonal weather events can lengthen already long travel times to access care. Expanding facilities to offer cancer care is expensive and requires staffing by skilled medical professionals, which are often in short supply. In this article, we propose a mathematical model to improve geographic access to cancer care by jointly considering expansions to care facilities and improvements to the road network. We model this as a multi-period stochastic facility location network design problem. In each period, a decision maker must simultaneously choose a set of facilities at which to add tertiary cancer services and a set of roads to improve while facing demand and travel time uncertainty. Once demand for cancer care and weather events are realized, patients observe road conditions and use the transportation network to travel towards the closed facility with available cancer services. We create a new path-based formulation of this problem and develop a new branch-price-and-cut algorithm with acceleration techniques that take advantage of this formulation's structure. We demonstrate our approach using Rwanda as a case study and show that the reductions in travel time to cancer care that are directly attributable to the road network improvements can be as high as 1 hour.

1 - How Close are We to Global Optimality in Cancer Radiotherapy Optimization? Benchmark Datasets and Algorithms for Measuring the Gap

Gourav Jhanwar, Memorial Sloan Kettering Cancer Center, New York, NY, United States, Mojtaba Tefagh, Qijie Huang, Linda Hong, Hai pham, Vicki Taasti, Seppo Tuomaala, Anthony Magliari, Michael Folkerts, Ying Zhou, Jie Yang, Saad Nadeem, Masoud Zarepisheh

Cancer radiotherapy treatment planning involves solving complex, large-scale optimization problems to determine patient-specific machine settings—such as the angle, intensity, and shape of radiation beams—that maximize tumor targeting while minimizing damage to healthy tissues. These problems are often non-convex and combinatorial, and the research community has developed a range of effective heuristic methods to solve them within strict clinical time constraints. More recently, AI-based approaches have shown promise in further improving planning efficiency and quality. Despite these advancements, two critical questions remain largely unanswered: 1) how close are the solutions obtained by existing methods—heuristic or AI-based—to the global optimum? and 2) how do different algorithmic approaches compare against each other in a standardized and reproducible setting?

To address this gap, we introduce **PortPy** (Planning and Optimization for Radiation Therapy in Python), an open-source framework that provides curated datasets derived from real patient cases, along with a suite of baseline algorithms ranging from classical heuristics to exact optimization techniques and modern AI-based methods. By offering a unified platform for evaluating and benchmarking algorithms, PortPy promotes transparency, reproducibility, and interdisciplinary collaboration in radiotherapy optimization research.

2 - Hybrid Risk Score Optimization Models for Patient Falls

Emmett Springer, Johns Hopkins University, Baltimore, MD, United States, Fardin Ganjkanloo, Erik Hoyer, Daniel Young, Kimia Ghobadi

Risk scores are prevalent in healthcare settings, and are simple classification models that allow clinicians to perform a fast and easy risk prediction with a linear combination. However, most risk score assessments are done manually, which is cumbersome and prone to human error. We design a set of risk score models with logistic loss to predict the risk of patients and stratify them into k classes. We augment and compare the models with varying levels of knowledge integration into the models for their accuracy, robustness, and computational expenses. We benchmark our models to predict the risk of patient falls in hospital settings, using data from three Johns Hopkins Health System hospitals. Our results show that all models improve compared to the current standard-of-care with up to a 29% increase in the area under the precision-recall curve (from 0.48 to 0.62) for the hybrid knowledge-based models. This translates to a 14.1% increase in specificity (0.71 to 0.81) with the same sensitivity and up to a 5.6% increase in sensitivity (0.88 to 0.93) with the same specificity. The hybrid knowledge-base models perform best in robustness, interpretability, and practical adaptation, while black-box models outperform other models in accuracy for the available dataset. Our models' insights highlight the critical importance of impaired mobility and cognitive impairments in predicting fall risk. This approach provides a robust foundation for health systems to systematically enhance inpatient fall prevention protocols and patient safety using data-driven optimization techniques, contributing to improved risk assessment and resource allocation in healthcare settings.

3 - An Augmented Mip Model for Home Care Scheduling

Jing Liu, Johns Hopkins University, Baltimore, MD, United States, Kimia Ghobadi

We develop a rolling-horizon Predict-Act-Learn framework for mixed-integer decision making under uncertainty, particularly for problems that arise in the healthcare operations domains. At each horizon, Predict estimates workload and disruption risk; Act solves a robust mixed-integer program to produce a base schedule; during execution, Learn uses a reinforcement-learning to refine the plan in response to realized conditions, and update models and uncertainty sets for subsequent horizons. This iterative process is designed to improve the reliability of the solutions when realizations deviate from expectations. We test this process for a home-care scheduling

problem with our partner collaborator (Vivia Cares; a home-care provider in Hawaii). We track and measure key performance metrics in provider-client matching, task assignment, patient preference, provider availability, and consistency in provider-client relationships, among others. We then develop a nominal optimization model to improve efficiency while balancing various tradeoff metrics in the problem, and adapt the Predict-Act-Learn approach for this problem to enable better adjustments to unforeseen changes and realization of the assumption.

4 - Using Large Language Models in Medical Analysis Tasks

Kimia Ghobadi, Johns Hopkins University, Baltimore, MD, United States, Felix Parker, Nimeesha Chan, Chi Zhang

Medical analysis tasks are often complex, multidimensional, and multimodal. In this talk, we explore the use of large language models (LLMs) in performing medical tasks. We particularly consider multimodal LLMs, and propose a hybrid foundation model (TsLLM) that integrates time series high-frequency signals with natural language models. This framework employs specialized techniques, including a patch reprogramming layer that aligns time series embeddings with the LLM's representation space, multiple covariate handling strategies for complex physiological relationships, and contextual prompting with patient-specific information. We evaluate TsLLM on various medical tasks, including electrocardiogram signals and outcome metrics.

1 - Solving Mixed Strategy Equilibrium Using Machine Learning: Evidence from Stock Exchange Fees

David Wu, Cornell University, Ithaca, NY, United States, Mao Ye

We study two-dimensional competition where both price and quality can vary continuously. In these models, only mixed-strategy Nash equilibria exist in the 2D space, as there is no single "best" product - only products that better align with individual consumer preferences. We exemplify this with stock exchanges, which compete for order flow by setting "make" and "take" fees. We develop an algorithm to solve for a mixed strategy equilibrium using neural networks that easily generalizes to any mixed strategy setting. Using the new method, we establish that competition increases overall market functioning through increased transactions. However, the majority of the increased surplus goes to one side of the market.

2 - Privacy-Enhanced Payment Systems

Brian Zhu, Columbia University, New York, NY, United States, Agostino Capponi, Michael Lee

Technological innovations enable digital privacy, but pose fundamental conflicts between freedom and control. We study the design of privacy-enhanced payment systems, valued for legitimate transactions but vulnerable to illicit financial activities. We distinguish two dimensions of privacy: identity privacy (masking the owner of an account) and transaction privacy (confidentiality in activity). Identity-private systems are suboptimal, enabling illicit operations to scale by distributing activity across multiple accounts. The optimal provision of transaction privacy is complex and tailored to the technological capabilities of illicit actors, but adopts a simple design when considering robustness to innovations in these technologies. Our framework generates a ranking of payment systems; public blockchains, despite abuse of identity-privacy, can dominate legacy systems under strong enforcement capabilities.

3 - Supply-Chain Finance: A Sharing Contract via the Return Function

David Yao, Columbia University, New York, NY, United States, Liao Wang, Shaohui Zheng

We develop a new "return function" R , as an alternative to the classical net profit function H of the newsvendor (NV) model. As random variables, R and H are equal in expectation (mean); in this sense, R can also be viewed as net profit. Yet, we show that R dominates H in concave order, and has other more desirable properties, e.g., increasing in the (realized) revenue. Based on the return function R , we propose a "sharing contract," between a producer and an investor, as an alternative to the traditional loan contract. That is, instead of the producer getting a loan from the investor, the producer and investor now share the realized value of R . The sharing contract is analyzed in detail for various objectives, including the traditional NV objective (linear), the risk measure CVaR, and a general concave utility. In all cases, it is shown that R always dominates H , in terms of increased benefits for both the producer and the investor. We also derive a real-time hedging strategy for the investor to mitigate the risk and compensate for profit loss in low-demand scenarios.

4 - Targeted Automation and Sustaining Human-AI Learning

William Schmidt, Emory University, Atlanta, GA, United States, Christina Imdahl, Kai Hoberg

In many decision processes, a planner must review and optionally adjust the recommendations that are generated by a decision support system (DSS). When the DSS is well-tuned to its task, adjustments by a planner can be rare and may even degrade the DSS's performance. Targeted automation could address these inefficiencies by predicting whether a planner will adjust a recommendation and improve performance of the system. The remaining recommendations can be automated. However, as more recommendations are automated, fewer will receive planner input. This may starve the prediction model of the observations it needs for retraining. Using four years of procurement ordering data from our research partner, a large materials handling equipment manufacturer, we develop and train machine learning algorithms that predict individual instances in which a planner will improve a DSS-generated procurement decision on order quantities. We mitigate the performance erosion that automation engenders by structuring the selection of the ML model's classification threshold similar to a newsvendor problem that balances the costs and benefits of under or over automating and accounts for the value of learning. Our approach automates around 84% of all DSS recommendations while retaining three times more improvements than random automation. Our research contributes to a broader debate on the allocation of decision authority between humans and algorithms, and creates a framework for targeted automation in financial and operational settings that balances the benefits of automation versus algorithmic learning.

1 - Corporate Venture Capital and Operational Performance of Medical Device Startups

George Ball, Operations and Decision Technologies, Kelley School of Business, Indiana University, Bloomington, IN, United States, Moyan Li, Haizhen Lin

Medical device startups are a pivotal dimension of new product innovation in the U.S. healthcare industry. Numerous innovative medical devices originate from startups that rely on two primary sources of external funding: independent venture capital (IVC) and corporate venture capital (CVC). CVC firms bring unique industry knowledge and incentives to startups that may impact startup's operational performance

outcomes. Using difference-in-difference models and an instrumental variable strategy, we study the effect of CVCs on the operational outcomes of medical device startups. We find that CVCs foster more startup product approvals, but once launched, these products experience worse product quality, indicating a double-edged sword to CVC funding. Post-hoc analyses reveal that this negative quality effect for startups is accentuated when CVC firms lack prior experience in the startups' product market, but is not impacted by the CVC firm's own product quality problems.

2 - Preannounced Regulatory Inspections: FDA Oversight and Drug Quality Risk

Zach Wright, Marriott School of Business, Brigham Young University, Provo, UT, United States, John Gray, George Ball, In Joon Noh

When inspecting a U.S. drug manufacturing facility, FDA inspectors arrive unannounced. However, in foreign countries, FDA inspectors provide significant advanced notice of their inspection, often many weeks or even months before arriving. We examine the impact of these differing FDA inspection approaches on inspection outcomes and drug quality. We first use data from unannounced U.S. and preannounced Indian FDA inspections. Using a matching analysis to mimic the FDA's model for selecting facilities for inspection, we find no significant difference in the odds of unannounced U.S. and preannounced Indian facilities receiving the most severe inspection outcome, implying relatively equivalent drug quality. Next, we examine previously unexplored data from two unannounced inspection pilots conducted by the FDA in India. These pilots enable us to disentangle whether the equivalent inspection outcome result is indicative of similar drug quality or a greater difficulty of detecting drug quality issues with preannounced inspections. We find that the odds of a facility receiving the most severe inspection outcome are significantly higher for unannounced inspections compared to preannounced inspections at the same facility in India. Finally, using a matched sample, we demonstrate potential consequences of preannouncing inspections in India, showing that the number of serious adverse events for drugs made in Indian facilities that experience preannounced inspections are significantly greater than for drugs made in matched facilities in the U.S. that experience unannounced inspections. Our findings provide the first quantitative empirical evidence that preannouncing FDA inspections may allow drug manufacturers to operate with greater and undetected quality risk.

3 - From Waste to Worth: Bridging the Gap Between Surplus and Shortage Outside the Traditional Pharmaceutical Procurement Channel

Ji Won Moon, Pennsylvania State University, University Park, PA, United States, Hui Zhao, Suvrat Dhanorkar

Drug *surplus* and *shortage* represent byproducts of inefficiencies in pharmaceutical supply chains that could help alleviate one another. Using proprietary data from an online B2B platform serving as an alternative, direct procurement channel for surplus drugs—most of which are *short-dated* (i.e., expiring within a year)—we empirically examine the benefits and caveats of this emerging marketplace for buyers (e.g., pharmacies, hospitals, providers) and sellers (i.e., manufacturers), particularly focusing on the dynamics between short-dated products and drug shortages as they influence sourcing patterns for medically necessary drugs in this unique environment.

4 - Impacts of a Non-Profit Intermediary on Reliability of Drug Supply

Junghye Lee, University of Notre Dame, Notre Dame, IN, United States, Jennifer Ryan, Hyoduk Shin, Daewon Sun

Generic drug shortages pose a growing and costly challenge in the U.S. This paper examines the impact of non-profit intermediaries, a recent entrant alongside traditional for-profit entities like group purchasing organizations, on the reliability of a shortage-prone generic drug supply chain. We develop an economic model relevant for mature off-patent generics with a limited supplier base. The entry of a non-profit introduces a new, potentially more reliable supplier. Our analysis reveals that while non-profit entry enhances supply reliability for its members, it does not guarantee overall supply chain improvement. We also find that increasing drug reimbursement rates may not necessarily improve supply reliability. Furthermore, our research provides guidance for non-profit organizations, highlighting that their effectiveness in mitigating shortages depends heavily on implementation strategies, including the degree of vertical integration. These findings offer critical insights for policymakers, as reimbursement increases are often proposed to address shortages.

5 - Changing Standards and Drug Shortages in the Pharmaceutical Industry

Ivan Lugovoi, Kuehne Logistics University, Hamburg, Germany, Enno Siemsen

Drug shortages can pose significant health risks; the failure of the market to fulfill the demand for life-saving drug treatments can endanger the health of patients. Using a proprietary dataset, we examine the relationship between changes in the quality standards of drugs and drug shortages through the lens of competition. We encode US-Pharmacopeia monograph changes to document changing quality standards in drug markets. Our analysis establishes that relaxing standards leads to an increase in the level of competition; however, tightening those standards does not lead to a similar decrease in competition. Further, we find a non-linearity in the relationship between the number of competitors and the risk of drug shortages. When that number is low, any new entrant will significantly decrease margins while not adding sufficient slack in the market capacity to absorb the failure of any incumbent to supply, leading to an increased drug shortage risk. However, as the number of competitors increases, the impact on profit margins is reduced; market shares of individual manufacturers decrease; and the reserve capacity in the market can more readily absorb the impact of a shortage by any individual competitor, decreasing the shortage risk again.

1 - Minimax Optimal Exploration for Nonparametric Multi-Arm Bandits

Brian Cho, Cornell Tech, New York, NY, United States, Nathan Kallus

We study the task of fixed confidence pure exploration in multi-arm bandits, which aims to minimize the sample complexity for finding a δ -correct answer for the exploration task (e.g. find the best arm). While pure exploration problems have primarily been studied from a theoretical perspective, the empirical performance of such methods suffer from overly conservative stopping times, restrictive parametric assumptions, and poor empirical performance. In this work, we provide a general approach for pure exploration tasks in the nonparametric setting where arms only satisfy boundedness and mean stationarity. From a theoretical perspective, we show that our setting is no harder than stationary Bernoulli bandits, and provide a novel anytime valid sequential test that (i) achieves asymptotic minimax optimality and (ii) ensures δ -correctness for a wide range of data generating processes. To improve the practical performance of our approach, we leverage asymptotic approximations of our testing method to reduce conservativeness and provide a batch schedule that maintains theoretical guarantees. Both on synthetic and real-world data, our approach drastically outperforms existing methods in the literature.

2 - Just Ramp-up: Unleash the Potential of Regression-Based Estimator for A/B Tests Under Network Interference

Qianyi Chen, Tsinghua University, Beijing, China, People's Republic of, Bo Li

A/B tests on modern platforms, including social networks and two-sided marketplaces, often encounter challenges from network interference. Extant research on causal inference under network interference based on single experiments often incurs substantial bias, particularly with complex interference. In this paper, we demonstrate the statistical benefit of merging the data of multiple experiments with different treatment proportions. Sequential experimentation with increasing traffic is often known as the ramp-up process in tech companies and is commonly applied due to operational reasons such as risk management and cost control. Beyond operational considerations, we find that regression-based estimators trained with such merged data achieve substantial bias reduction even with simple randomization schemes. Since the ramp-up process

is standard practice, our methodology does not require additional experiment resources, providing a true plug-and-play solution that is easy to implement. We present a rigorous theoretical analysis of the bias and variance for the linear regression estimator of the global average treatment effect (GATE) under general linear network interference. We show that bias plays a dominant role in practical settings, and we highlight the bias reduction achieved by merging data from experiments with different treatment proportions. We provide an intuitive explanation for the bias reduction and, through the same lens, illustrate the synergistic effect of pooling experiments and cluster-level randomization. Furthermore, we consider a more advanced estimator based on graph neural networks (GNN). Through extensive simulation studies across novel and challenging scenarios, we show that the regression-based estimator benefits remarkably from our methodology, achieving outstanding statistical performance.

3 - Dynamic Local Average Treatment Effects

Ravi Sojitra, Stanford University, Stanford, CA, United States, Vasilis Syrgkanis

We enable identification, estimation, and inference for Local Average Treatment Effect (LATE) estimands in multiple time period settings with noncompliance and allow for treatment dynamics. Dynamics occur when treatment is encouraged in each time period depending on previous encouragements, treatments, and states (e.g. short term outcomes and time varying covariates). Although one may hope to leverage estimates of the effects of switching from one sequence of treatments to another, such quantities are not estimable under noncompliance and standard identifying assumptions for dynamic settings and LATEs. We introduce two conditions to enable identification of Dynamic LATEs that quantify effects for subpopulations who would comply with encouragements. First, we show that One Sided Noncompliance enables identification of all Dynamic LATEs corresponding to treating in a single period only. Second, further adding Staggered Adoption enables identification of effects of treating in multiple time periods. In general, the second result holds when the treatment effect of not continuing to comply is uncorrelated with whether one continues complying. We also show that a sequential extension of Monotonicity in Imbens and Angrist (1994) is not sufficient for the first result and an additional assumption is necessary for the second result. Finally, we use the automatic debiased machine learning framework to perform plug-in estimation and inference based on our identification results.

1 - Closed-Form Formulas for Cluster Sizing for Two-Level Hierarchical Networks with Source Routing

Eric Rosenberg, Seton Hall University, South Orange, NJ, United States

In a two-level hierarchical network, nodes are grouped into clusters. A node in one cluster sees the entire topology of that cluster, but only a summarized view of other clusters. With source routing, the source node of a connection does an initial route computation based on its view of the network, and additional route computations are performed as the connection makes its way towards the destination. We study the problem of choosing the number of clusters to minimize the total complexity of all the path computations required to compute a path from a source node to a destination node. We show that, under mild conditions, for all sufficiently large networks two-level hierarchical routing is superior to flat network routing. Utilizing the duality theory of geometric programming, we provide a closed-form solution estimate for the number of clusters to minimize the total routing complexity. We also provide a closed-form expression for a lower bound on the minimal total complexity. We illustrate the modelling assumptions for a variety of networks. Computational results for a range of network sizes and parameters show that our solution estimate yields near-optimal results.

2 - Customer Relationship Management for Intangible Goods: the Effects of Customer Responsiveness, Engagement, and Reactance on Customer Rejection

Ameya Badve, City University of New York, New York, NY, United States, Ramakrishnaiah Bezawada, Karthik Sridhar

ABSTRACT

In a market driven by technology and information, the consumption of intangible goods has gone up. Customer relationship management for intangible goods is quite different from tangible goods. This article introduces a conceptual framework of customer relationship management for intangible goods that captures customer relationship using a novel construct called customer rejection and hypothesizes the effects of customer commitment, customer engagement, customer responsiveness, and customer reactance on customer rejection. The authors empirically test the hypotheses using data from a mobile app consumption. They find that while the risk of customer rejection is mitigated by the higher levels of customer commitment, customer engagement, and customer responsive, such risk is increased with a higher level of customer reactance. However, the increased risk of customer reactance can be managed using active customer engagement and customer responsiveness. Finally, exploring the different types of customer rejection, the authors provide strategies for hard and soft customer rejections based on product usage and customer lifetime. This research provides theoretical and managerial insights into the customer relationship management for intangible goods.

3 - Predicting Customer Lifetime Value and Segmenting Clients Using Machine Learning in the Payment Industry

Reza Maihami, Mercer University, Atlanta, GA, United States, Ehsan Ahmadi, Priya Gandhi, Maria Gomez

In the rapidly evolving payment industry, understanding customer value is critical for optimizing resource allocation and long-term growth. This article develops a machine learning-based framework to predict Customer Lifetime Value (CLTV) using historical merchant data in a non-contractual, continuous interaction setting. Leveraging the BG/NBD and Gamma-Gamma models, we estimate future purchasing frequency and monetary value for each customer. The predicted CLTV values are then used to segment customers via clustering analysis, uncovering distinct behavioral profiles. The resulting clusters—Diamond, Gold, Silver, and Bronze—highlight significant disparities in revenue contribution and engagement patterns. These insights enable targeted marketing strategies and personalized engagement efforts, empowering payment companies to retain high-value customers and uplift lower-tier segments. Our approach demonstrates the power of data-driven decision-making in customer relationship management and strategic planning.

4 - Modeling Willingness to Collaborate for Resource Sharing in Food Bank Networks

Rashik Siddiquee, North Carolina State University, Raleigh, NC, United States, Julie Ivy, Osman Ozaltin

The food bank network consists of numerous independently operated partner agencies that support food-insecure populations using donations from both individual sources and the central food bank. While collaboration among these agencies, through the sharing of resources and information, has the potential to enhance overall network resilience, such collaboration is often informal, unstructured, and highly variable across agencies. The degree to which an agency engages in this collaborative behavior is influenced by internal capacity, trust, technological capability, and organizational culture. This study seeks to quantify each agency's willingness to collaborate (WTC). We introduce a data-driven framework that models WTC as a behavioral parameter, estimated using regression and machine learning methods on observable features such as supply stability, communication practices, and historical cooperation patterns. By explicitly modeling willingness to collaborate, this research contributes a novel behavioral dimension to humanitarian logistics and offers insights for designing stronger, more cooperative food distribution networks. It also performs a case study on the agencies affiliated with the Food Bank of Central and Eastern North Carolina that serve Wake County.

5 - Decoding the Code: Revealing Block Usage Patterns for Design- and Context-Sensitive Computational Thinking (CT) Assessment in Game-Based Constructionist Learning

Amir Abdollahi, Northeastern University, Boston, MA, United States

Computational thinking (CT) is foundational in contemporary education, and game-based constructionist learning (GBCL) has proven effective in fostering CT, especially through block-based programming (BBP). However, the creative nature of game design complicates evaluating student-created artifacts. While automated CT metrics are helpful, they often overlook nuances in BBP. We analyzed 483 Scratch projects to uncover coding patterns, model artifacts' genre, and assess their combined impact on CT

outcomes. We found biases in the way students explore and use Scratch blocks and identified two clusters of coding patterns, strongly correlating with game genres (design aspect), demographic factors (e.g., Scratch experience, gender), and CT scores (learning aspect). Visual block categories (e.g., Looks) were key in decoding game genres, while logical categories (e.g., Data) were essential in clustering coding patterns and predicting CT uptake. These findings present opportunities for design- and context-sensitive CT assessments, paving the way for adaptive CT assessments in GBCL curricula.

Human-AI Collaboration for Decision-Making

Invited Session

Decision Analysis Society

Chair: Shixiang Woody Zhu, Carnegie Mellon University, Pittsburgh, PA, United States

Co-Chair: Shixiang Woody Zhu, Carnegie Mellon University, Pittsburgh, PA, United States

Co-Chair: Holly Wiberg, Carnegie Mellon University, Pittsburgh, PA, 15213, United States

1 - Human-Guided Generate-Then-Optimize: a Unified Framework for Decision Refinement and Uncertainty Quantification

Minxing Zheng, Carnegie Mellon University, Pittsburgh, PA, United States

We introduce a Human-Guided Generate-Then-Optimize framework that integrates human preference feedback into decision-making pipelines under parameter uncertainty and distributional shift. Building on the predict-then-optimize paradigm, we model uncertainty over objective parameters with a generative model and obtain human preferences over candidate decisions. We first test for distributional shifts between human feedback and historical data; when shifts are detected, we refine the generative model via reward-based updates. Our framework improves both decision alignment and the efficiency of the uncertainty set of estimated parameters under distributional shift. This provides a unified approach for decision refinement, uncertainty-aware optimization, and adaptive alignment to human preferences in dynamic environments.

2 - The Value of AI Advice: Personalized and Value-Maximizing Ai Advisors are Necessary to Reliably Benefit Experts and Organizations

Nicholas Wolczynski, UT Austin, Austin, TX, United States, Maytal Saar-Tsechansky, Tong Wang

Despite advances in AI's performance and interpretability, AI advisors can undermine experts' decisions and increase the time and effort experts must invest to make decisions. Consequently, AI systems deployed in high-stakes settings often fail to consistently add value across experts and organizations and can even diminish the value that experts alone provide. Beyond harm in specific domains, such outcomes impede progress in research and practice, underscoring the need to understand when and why different AI advisors add or diminish value. To bridge this gap, we stress the importance of assessing the value AI advice brings to real-world contexts when designing and evaluating AI advisors. Building on this perspective, we characterize key pillars -- pathways through which AI advice impacts value -- and develop a framework that incorporates these pillars to create reliable, personalized, and value-adding advisors. Our results highlight the need for value-driven development of AI advisors that advise selectively, are tailored to experts' unique behaviors, and are optimized for context-specific trade-offs between decision improvements and advising costs. They also reveal how the lack of inclusion of these pillars in the design of AI advising systems may be contributing to the failures observed in practical applications.

3 - Llm Feedback on Science: a Large-Scale Randomized Field Experiment

Binglu Wang, Northwestern University, Evanston, IL, United States, Weixin Liang, Jiahui Xue, Yuhui Zhang, Hancheng Cao, Dashun Wang, Yian Yin

The transformative impact of Large Language Models (LLMs) across various sectors has demonstrated their potential to enhance productivity and facilitate complex decision-making processes, significantly altering innovation workflows. Despite their widespread adoption in commercial and consumer domains, the integration of LLMs into the unique processes of scientific discovery and innovation has been minimally explored. In this study, we present evidence from a large-scale randomized field experiment involving 34K recent preprints authored by 50K scholars across eight STEM fields and 136 global regions. We find that LLM-generated feedback significantly influences the revision of preprints and encourages the continued use of LLMs in academic writing. Notably, the impact of LLMs varies by region and domain expertise, highlighting both the promise and the inequality in their adoption. These findings suggest that, when thoughtfully deployed, LLMs can help democratize access to high-quality feedback and support more inclusive innovation practices on a global scale.

4 - Using Machine Learning to Diagnose Dynamic Human Decision Making: Insights from a Bioinnovation Context

Ziqian Ding, Carnegie Mellon University, Pittsburgh, PA, United States, Zhaohui Jiang, Param Singh

In various policy and business settings, humans are making high-stakes, dynamic decisions by managing trade-offs over time. Meanwhile, there are advancements in machine learning algorithms that are designed to optimize actions explicitly considering dynamic trade-offs. This paper introduces a framework demonstrating how these ML algorithms can be leveraged to diagnose and improve human decision-making in complex, dynamic settings. We implement this framework in a biomedical innovation context, where bioscientists make resource allocation decisions to maximize scientific success across a large number of projects over a span of 16 years. These decisions involve balancing immediate gains (exploitation) with the potential for learning across projects (exploration) in each period. We train a Combinatorial Neural Upper Confidence Bound (CN-UCB) model and use it as a benchmark to diagnose the decision-making processes of scientists. To understand the sources of inefficiencies, we estimate a dynamic structural model of human behavior, capturing deviations from the algorithm along two key dimensions: exploration-exploitation strategies and project success predictions. Interestingly, we find that scientists exhibit higher prediction errors than our algorithm, and tend to over-explore---they attempt too many projects they are unfamiliar with. Besides, humans on average allocate fewer trials to a project, and thus they are less likely to "delve deep" into a project than the algorithm. Finally, we find that unilaterally improving one of the two types of inefficiency can not fully recover the improvements of the algorithm over humans, emphasizing the importance of correcting both prediction errors and suboptimal explorations in diagnosing dynamic decision making.

5 - Validating LLM-as-a-Judge Systems in the Absence of Gold Labels

Luke Guerdan, Carnegie Mellon University, Pittsburgh, PA, United States

The LLM-as-a-judge paradigm, in which a judge LLM system replaces human raters in making decisions about the quality of other generative AI (GenAI) system outputs, plays a critical role in scaling and standardizing GenAI evaluations. To validate such judge systems, evaluators assess human--judge agreement by first collecting multiple human ratings for each item in a validation corpus, then aggregating the ratings into a single, per-item gold label rating. In many cases, however, items or rating criteria may be vague or ambiguous, or admit multiple interpretations, so a given rater (human or LLM) may deem multiple answers "reasonable" or "correct." We call such rating tasks indeterminate. Problematically, many indeterminate rating tasks rely on forced-choice elicitation, whereby raters are able to select only one answer option for each item. In this paper, we introduce a framework for LLM-as-a-judge validation for indeterminate rating tasks. We draw theoretical connections between different measures of judge system performance under different human--judge agreement metrics, and different rating elicitation and aggregation schemes. We demonstrate that differences in how humans and LLMs resolve indeterminacy in forced-choice rating tasks heavily bias LLM-as-a-judge validations. Through extensive experiments involving 11 real-world rating tasks and 8 commercial LLMs, we show that standard validation approaches select judge systems that are highly suboptimal, performing as much as 30% worse than judge systems selected by alternatives we propose. We conclude with concrete recommendations for more principled and reliable approaches to LLM-as-a-judge validation.

Decision Making in E-Commerce

Invited Session

MSOM: Supply Chain

Chair: Jussi Keppo, National University of Singapore, Singapore, Singapore

Co-Chair: Bretislav Hajek, National University of Singapore, Singapore, Singapore

1 - Same-Day OR Next-Day? Transparent TIME-Dependent Shipment Pricing for E-Fulfillment

Uta Mohring, Eindhoven University of Technology, Eindhoven, Netherlands, Melvin Drent, Ivo Adan, Willem van Jaarsveld

Fulfilling online orders quickly is increasingly vital in e-commerce, with many companies offering same-day shipment services to meet rising customer expectations. However, companies risk overpromising their shipment services when the offered shipment options and corresponding fees are not aligned with the ability to fulfill these orders, leading to delayed orders and customer dissatisfaction. Indeed, fulfillment centers may be unable to hand over all orders to the carriers by the agreed deadlines. We propose a transparent time-dependent shipment policy where shipment options and fees depend on the remaining time until the next shipment deadline but are consistent each day. Such a shipment policy can influence customers' shipment preferences to help balance workload while remaining marketable to customers. We build a parsimonious model of a stochastic e-commerce fulfillment center operating this transparent time-dependent shipment policy, where customers arrive according to a Poisson process. We present an exact steady-state performance analysis based on a periodic Markov chain model and establish structural properties of the optimal shipment policy. Motivated by its practical appeal, we propose the two-level time-dependent shipment policy that differentiates two fees for same-day shipment. Numerical results indicate that this shipment policy achieves near-optimal solutions and clearly outperforms benchmark policies prevalent in practice that rely on time-independent fees. This work provides actionable guidance for e-commerce companies to better balance demand for same-day and next-day shipment with the available capacity in their fulfillment centers. Our transparent time-dependent shipment policy, designed to be disclosed to customers, offers a simple and customer-friendly solution.

2 - Study on the Overlap of Finite Mixture Modeling of Categorical Sequences

Yingying Zhang, Western Michigan University, Kalamazoo, MI, United States, Xuwen Zhu

Categorical sequences play an essential role in many fields, but research, especially the cluster analysis of this type of data, is limited. In this paper, the overlap character of categorical sequences is quantified. The proposed methodology involves derivation and calculation of the exact overlap expressed as the sum of misclassification probability between two clusters. Based on the calculated overlap value, algorithms are designed to simulate clusters satisfying user-defined overlap. The application of the proposed method is achieved through internet users' web-browsing sequences. Customers' internet navigation patterns are recorded and classified into distinct clusters. By investigating the overlap feature among various clusters, the similarities and dissimilarities of web-browsing behaviors can be clearly observed, which gives valuable insights for platforms for targeted advertising or group-specific recommendations.

3 - Information Design for Supply Chains with Priority Suppliers

Rufat Ismayilov, ESMT GmbH, Berlin, Germany, Ozan Candogan, Huseyin Gurkan, Boxuan Zhou

This paper studies the problem of information design in a supply chain where a retailer faces two upstream suppliers and must privately communicate market demand information. One supplier holds a priority advantage in fulfilling orders over the other. The retailer's challenge is to design an information disclosure policy that accounts for this priority structure while minimizing the expected lost sales cost. We model the interaction between the retailer and the suppliers using a Bayesian persuasion framework, where the retailer privately sends demand signals to each supplier, who then decides on their production quantities. We explore how the retailer should optimally inform suppliers with different priority levels. Our analysis reveals that the retailer should strategically favor the supplier with lower priority by providing more informative signals, while keeping the higher-priority supplier relatively less informed.

4 - Ad Feeding on A Consumer-to-Consumer Media Platform

Xuying Zhao, Texas A&M University, College Station, TX, United States, Zheyin (Jane) Gu

In this study, we investigate a C2C media platform's strategy to maximize advertising revenue under the threat of self-posted misinformation. Our model captures content providers' strategic decisions to post content on the platform as well as consumers' decisions to view content on the platform.

5 - Inventory Management and Assortment Planning In An Apparel Closed-Loop Supply Chain

Heletjé Van Staden, UCD Michael Smurfit Graduate Business School, Monkstown, Ireland, Hannah Yee

We consider an apparel rental platform with a fixed membership pool and non-stationary demand with partial observability. The platform aims to optimize garment purchasing decisions to best meet customer demand while minimizing operational costs. We model the problem as an ambiguous partially observable Markov decision process, which allows us to account for both uncertainty regarding the underlying demand distributions governing the demand and ambiguity regarding the platform members' demand preferences. We use reinforcement learning to approximate the optimal inventory control and assortment decisions. For the instances considered, we find that the algorithm improves on the static order up to policy by 6%, on average. By adjusting the inventory position to changing demand, our policy is able to limit dissatisfaction among members at the expense of holding slightly more inventory. Our work contributes to the closed-loop supply chain literature and can be used to support rental platforms with inventory and assortment procurement decisions given ambiguous and uncertain trends in customer preferences.

6 - Strategic Enforcement of Noncompete Agreements with Rival Active Differentiation

Kunyang Li, Shanghai Jiao Tong University, Shanghai, China, People's Republic of, Wenhui Zhao

Talent loss due to poaching—where employees leave to join competing firms—poses multifaceted risks to firms, particularly the leakage of trade secrets and tacit knowledge. To mitigate these risks, many firms globally adopt noncompete agreements (NCAs). However, NCAs embody an inherent conflict between firms seeking to protect intellectual assets and employees' right to mobility, fueling ongoing debate over their adoption and regulation. Existing discussions on how should the mother-firm design and use NCA to restrict the flow of talents to its competitors to suppress competitions, while overlooking the significance and necessity of the joint development of talents career and industries. We develop a game-theoretical modeling framework to capture the interaction between a firm and a talent, and examine the enforcement strategy of NCAs with active rival differentiation. Our findings indicate that the departure of talents can incentivize poaching firms to pursue differentiation strategies. This reduces the scope of noncompete restrictions and thereby encourages firms to be more supportive of talent mobility. Our findings provide valuable insights for both firms and regulators, offering guidance on structuring NCAs to balance trade secrets protection and employee mobility, thereby fostering talent development and industry growth.

Strategic Queueing

Invited Session

MSOM: Service Operations

Chair: Ricky Roet-Green, Simon Business School, University of Rochester, Rochester, NY, United States

1 - Equilibrium and Regulation in Strategic Queues via Stochastic Approximation

Ran Snitkovsky, Collier School of Management, Tel Aviv University, Tel Aviv, Israel

Regulating admission in non-Markovian queueing systems often requires simulation, as closed-form solutions are typically unavailable. This challenge is further compounded when customers act strategically—making join/balk decisions based on expected delays—thereby inducing a feedback loop between customer behavior and system performance. In this talk, I introduce stochastic approximation algorithms designed for such settings and demonstrate their effectiveness in two canonical regulation problems: (1) maximizing social welfare and (2) maximizing revenue. The proposed approach exploits the regenerative structure of the underlying queueing process, allowing for asymptotic performance guarantees under mild regularity conditions.

2 - Observable Multi-Class Priority Queues: Rational Abandonment Strategies

Philipp Afèche, University of Toronto, Rotman School of Management, Toronto, ON, Canada, Simon Laumer

We study two questions regarding rational customers' abandonment behavior in observable multi-class priority queues: (1) What are the characteristics of an equilibrium in customers' join/balk/abandonment decisions? (2) How do these characteristics depend on customer attributes?

We consider an observable multi-class M/M/1 priority queue with strict preemptive priorities. The service order among customers in the same class is first-come-first-served. The service rate is equal for all customers. Each customer belongs to one of p priority classes, where p is an arbitrary integer. Each class is characterized by its arrival rate, linear delay cost rate and service reward. The arrival processes are exogenous, but upon arrival, every customer is forward-looking and solves an optimal stopping problem to maximize their expected utility (expected reward minus delay cost). The customer decides whether to balk or join, and if they join, whether to stay or abandon at every state transition (service completion or customer arrival), considering the future expected system evolution.

We provide analytical sufficient conditions for the equilibrium abandonment behavior to have the following threshold structure: (i) Each class has a threshold on the queue position of the last customer in that class, such a customer abandons only if their position goes above this threshold. (ii) These thresholds decrease in the priority level of the class, i.e., higher priority has a (weakly) smaller threshold.

These sufficient conditions depend explicitly on key model parameters (offered loads, delay costs and rewards of the different classes) and provide intuition on the system economics.

3 - Dynamic Pricing and Release TIME Control for Service Systems

Kevin Shang, Duke University, Durham, NC, United States, Chen-An Lin, Peng Sun

This paper studies a mechanism design problem for a single-server queue where customers are served in a first-come-first-serve (FCFS) manner. Customers are heterogeneous and have private information about their valuation of immediate service and sensitivity to waiting time. Impatient (versus patient) customers are more sensitive to delays and place higher value on immediate service. The service provider offers a history-dependent menu, with each menu item specifying a price and release time for each type of customer, aiming to maximize the long-run average revenue. We show that the optimal menu depends on history only through the system's completion time and consists of four possible strategies: delaying patient customers, pooling all customers, screening customers (serving one type and rejecting the other), and rejecting all customers. In particular, it is optimal to delay the release time of patient customers beyond the current service completion time if and only if the completion time is below a certain threshold. This strategic delay enables the provider to charge a premium to impatient customers, thus increasing revenue. Notably, the delayed release time is set to a fixed value, independent of the current completion time, which simplifies implementation. Under the screening strategy, the decision to serve patient or impatient customers depends on a trade-off between the utility a customer derives from joining the queue and the negative externality caused by increased congestion. These findings highlight how timing and differentiated pricing can be used to optimize revenue in queues with strategic delays.

4 - When Strategic Customers Meet Strategic Servers: Individual and Social Optimization in Many-Server Queueing Systems

Ragavendran Gopalakrishnan, Smith School of Business at Queen's University, Kingston, ON, Canada, Yueyang Zhong, Amy Ward

We initiate the study of interactions between strategic customers and strategic servers in many-server queueing systems. In the seminal works of Naor (1969) and Knudsen (1972), arriving customers decide whether to join the system based on a trade-off between their reward from service and cost of waiting, while servers operate at fixed exogenous rates. The joining threshold (maximum queue length) induced by self-interested customers at equilibrium is higher than socially optimal (i.e., they "over-join"), a result known as Naor's inequality. This is because they fail to internalize the congestion externality they impose on other customers. Although Naor's inequality is robust across a wide spectrum of queueing models, its validity when servers are also strategic (in choosing their work-speeds) is unknown. Within a large-system asymptotic framework, we show that strategic servers provide slower than socially optimal service at equilibrium, thereby deterring customers from joining the system, and when this effect outweighs customers' tendency to over-join, Naor's inequality is reversed. Next, we propose a scheme that charges an entry fee from customers and offers a performance-based compensation for servers, which realigns individual incentives with the social optimum. Finally, we analyze how the overall welfare gains at the social optimum (relative to the equilibrium) are distributed across customers and servers, in order to unearth potential equity trade-offs in policy design.

Multi-Agent Learning in Markets

Invited Session

Manufacturing and Service Operations Management (MSOM)

Chair: Negin Golrezaei, Massachusetts Institute of Technology, Cambridge, MA, United States

Co-Chair: Rigel Galgana, Massachusetts Institute of Technology, Cambridge, MA, United States

1 - Heterogeneous Multi-Agent Bandits with Parsimonious Hints

Amirmahdi Mirfakhhar, Umass Amherst, Amherst, MA, United States, Xuchuang Wang, Jinhang Zuo, Yair Zick, Mohammad Hajiesmaili

We study a hinted heterogeneous multi-agent multi-armed bandits problem (HMA2B), where agents can query low-cost observations (hints) in addition to pulling arms. In this framework, each of the M agents has a unique reward distribution over K arms, and in T rounds, they can observe the reward of the arm they pull only if no other agent pulls that arm. The goal is to maximize the total utility by querying the minimal necessary hints without pulling arms, achieving time-independent regret. We study HMA2B in both centralized and decentralized setups. Our main centralized algorithm, GP-HCLA, which is an extension of HCLA, uses a central decision-maker for arm-pulling and hint queries, achieving $O(M4K)$ regret with $O(MK\log T)$ adaptive hints. In decentralized setups, we propose two algorithms, HD-ETC and EBHD-ETC, that allow agents to choose actions independently through collision-based communication and query hints uniformly until stopping, yielding $O(M3K2)$ regret with $O(M3K\log T)$ hints, where the former requires knowledge of the minimum gap and the latter does not. Finally, we establish lower bounds to prove the optimality of our results and verify them through numerical simulations.

2 - Markets with Heterogeneous Agents: Dynamics and Survival of Bayesian vs. No-Regret Learners

Yoav Kolumbus, Cornell University, Ithaca, NY, United States, David Easley, Eva Tardos

We analyze the performance of heterogeneous learning agents in asset markets with stochastic payoffs. Our main focus is on comparing Bayesian learners and no-regret learners who compete in markets and identifying the conditions under which each approach is more effective. Surprisingly, we find that low regret is not sufficient for survival: an agent can have regret as low as $O(\log T)$ but still vanish when competing against a Bayesian with a finite prior and any positive prior probability on the correct model. On the other hand, we show that Bayesian learning is fragile, while no-regret learning requires less knowledge of the environment and is therefore more robust. Motivated by the strengths and weaknesses of both approaches, we propose a balanced approach to utilizing Bayesian updates that improves robustness and adaptability to distribution shifts, providing a step toward a "best-of-both-worlds" learning approach. The method is general, computationally efficient, and easy to implement. Finally, we formally establish the relationship between the notions of survival and market dominance studied in economics and the framework of regret minimization, thus bridging these theories. More broadly, our work contributes to the understanding of dynamics with heterogeneous types of learning agents and their impact on markets.

3 - Allocating Public Goods via Dynamic Max-Min Fairness: Long-Run Behavior and Competitive Equilibria

Chido Onyeze, Cornell University, Ithaca, NY, United States, Siddhartha Banerjee, Giannis Fikioris, Eva Tardos

Dynamic max-min fair allocation (DMMF) is a simple and popular mechanism for the repeated allocation of a shared resource among competing agents: in each round, each agent can choose to request or not for the resource, which is then allocated to the requesting agent with the least number of allocations received till then. Recent work has shown that under DMMF, a simple threshold based request policy enjoys surprisingly strong robustness properties, wherein each agent can realize a significant fraction of her optimal utility irrespective of how other agents' behave. While this goes some way in mitigating the possibility of a 'tragedy of the commons' outcome, the

robust policies require that an agent defend against arbitrary (possibly adversarial) behavior by other agents. This however may be far from optimal compared to real world settings, where other agents are selfish optimizers rather than adversaries.

Our work aims to bridge this gap by studying the existence and properties of equilibria under DMMF. To this end, we first show that despite the strong robustness guarantees of threshold based strategies, no Nash equilibrium exists when agents participate in DMMF using such strategies. On the positive side, however, we show that for the symmetric case, a simple data-driven request policy guarantees that no agent benefits from deviating to a different fixed threshold policy. Furthermore, we show that the resulting equilibrium outcomes from this strategy can be significantly better compared to what follows from the robustness guarantees.

4 - Learning to Bid in Forward Electricity Markets Using a No-Regret Algorithm

Dorsa Majdi, Stanford University, Palo Alto, CA, United States, Arega Getaneh Abate, Jalal Kazempour, Maryam Kamgarpour

It is a common practice in the current literature of electricity markets to use game-theoretic approaches for strategic price bidding. However, they generally rely on the assumption that the strategic bidders have prior knowledge of rival bids, either perfectly or with some uncertainty. This is not necessarily a realistic assumption. This paper takes a different approach by relaxing such an assumption and exploits a no-regret learning algorithm for repeated games. In particular, by using the \emph{a posteriori} information about rivals' bids, a learner can implement a no-regret algorithm to optimize her/his decision making. Given this information, we utilize a multiplicative weight-update algorithm, adapting bidding strategies over multiple rounds of an auction to minimize her/his regret. Our numerical results show that when the proposed learning approach is used the social cost and the market-clearing prices can be higher than those corresponding to the classical game-theoretic approaches. The takeaway for market regulators is that electricity markets might be exposed to greater market power of suppliers than what classical analysis shows.

Current Topics in The Energy Transition

Invited Session

MSOM: Sustainable Operations

Chair: Christian Kaps, Harvard Business School, Cambridge, MA, United States

1 - Utilities's Managed Home Charging Programs for Electric Vehicles

Ali Fattahi, Johns Hopkins University, Baltimore, MD, United States

Experts estimate 20 million electric vehicles will be on U.S. roads by 2030, and the majority (around 80%) of the electric vehicle drivers will use home charging. Many utilities are designing managed home charging programs to centrally manage charging times to reduce cost, avoid new and aggravated peaks and blackouts, and ensure grid stability. These managed home charging programs are either active, in which the utility continuously controls the charging while the vehicle is plugged in, or passive, in which the participants decide when to charge based on preannounced low-rate episodes. We study jointly designing and executing these active and passive programs. We present a program-design model, which produces a menu of the charging programs, tailored for each driver type, and a load-management model, which dynamically manages the load supply to each individual participant. The load-management model consists of a large number of nonhomogeneous participants, and it is a large-scale mixed-integer nonlinear stochastic problem. We present an effective approximation method, conduct thorough theoretical and numerical analyses of our approximation, and provide worst-case bounds for its error components. Our methodology provides detailed insights on the amount and timing of the improvements achievable in cost and demand variability by offering managed home charging programs, and by customizing the passive programs. It also offers detailed insights on the significance of the tradeoff between cost and demand variability. We find promoting a culture of charging electric vehicles every night may significantly increase utilities' total cost if passive programs have high participation levels.

2 - Behavioral Generative Agents for Energy Operations

Omer Karaduman, Stanford University, Stanford, CA, United States, Kuang Xu, Cong Chen

Accurately modeling consumer behavior in energy operations remains challenging due to inherent uncertainties, behavioral complexities, and limited empirical data. This paper introduces a novel approach leveraging generative agents--artificial agents powered by large language models--to realistically simulate customer decision-making in dynamic energy operations. We demonstrate that these agents behave more optimally and rationally in simpler market scenarios, while their performance becomes more variable and suboptimal as task complexity rises. Furthermore, the agents exhibit heterogeneous customer preferences, consistently maintaining distinct, persona-driven reasoning patterns. Our findings highlight the potential value of integrating generative agents into energy management simulations to improve the design and effectiveness of energy policies and incentive programs.

3 - Selecting Battery Portfolios: the Value of Heterogeneity

Joonho Bae, University of Michigan Ross School of Business, Ann Arbor, MI, United States, Roman Kapuscinski, John Silberholz

Given rapid technological advancements and the growing availability of batteries, including retired batteries from electric vehicles, battery operators are faced with the opportunity to invest in heterogeneous systems, also known as "hybrid energy storage systems." These systems are constructed using battery modules of different types, ages, and capacity ratings. However, making this decision is complex due to various factors, such as battery degradation or energy losses, which significantly affect the projected benefits of a diverse battery portfolio. Specifically, this study focuses on contingency applications, such as backup battery power systems, where the battery operator commits to supplying energy during emergencies, in the presence of uncertainties. This paper uses analytical modeling to systemically characterize the benefits of heterogeneity in battery systems and establish general lessons.

4 - Two-Sided Subsidies for Electric Vehicles: the Role of Regional Characteristics

Saed Alizamir, University of Virginia, Charlottesville, VA, United States, Michael Blair, Runyu Tang

Electric vehicles (EVs) are touted as the future of urban transportation and a solution to climate change. Despite their benefits, EV adoption faces significant headwinds because of high prices, range anxiety, and limited charging infrastructure. To overcome these obstacles, many governments have introduced financial incentives that directly support EV purchasers or hybrid policies that subsidize both buyers and charging station developers. Given the global variation in policies, the key questions are what type of subsidy program is optimal, and how does the optimal program change with the local market characteristics. Answering these questions and understanding the benefits of localized hybrid subsidies is the focus of this paper.

We characterize the optimal hybrid subsidy mechanism and identify conditions under which incentivizing EV buyers alone is suboptimal. We find that the two subsidy instruments can be substitutes or complements, depending on the net benefit of EVs to society at large. Leveraging data from Norway, we calibrate key model parameters and estimate that policies optimized for each region can enhance social welfare by up to 25% compared with national-level policies. Our model offers policy recommendations on how legislators should adjust EV subsidies considering regional characteristics.

Learning and Optimization in Revenue Management

Invited Session

Revenue Management

Chair: Ruihao Zhu, Cornell University, Ithaca, NY, United States

Co-Chair: Hanzhang Qin, National University of Singapore, Singapore, Singapore

1 - Contextual Online Decision Making with Infinite-Dimensional Functional Regression

Haichen Hu, Massachusetts Institute of Technology, Cambridge, MA, United States, Rui Ai, Stephen Bates, David Simchi-Levi

Contextual sequential decision-making is fundamental to machine learning, with applications in bandits, sequential hypothesis testing, and online risk control. These tasks often rely on statistical measures like expectation, variance, and quantiles. In this paper, we propose a universal algorithmic framework that learns the full underlying distribution, enabling a unified approach to all contextual online decision-making problems. The challenge lies in the uncountably infinite-dimensional regression, where existing contextual bandit algorithms all yield infinite regret. We innovatively propose an efficient infinite-dimensional functional regression oracle for contextual cumulative distribution functions (CDFs) and model every datum as a combination of context-dependent CDF basis functions. Our analysis reveals that the decay rate of the eigenvalue sequence of the design integral operator governs the regression error rate, and consequently, the utility regret rate. We can also recover the existing optimal rate in contextual bandits literature with finite-dimensional regression and so as exponential decay. We also provide a numerical method to compute the eigenvalue sequence of integral operators, enabling the practical implementation of our framework.

2 - How Humans Help LLMs: Assessing and Incentivizing Human Preference Annotators

Xiaocheng Li, Imperial College Business School, London, United Kingdom

Human-annotated preference data play an important role in aligning large language models (LLMs). In this paper, we investigate the questions of assessing the performance of human annotators and incentivizing them to provide high-quality annotations. We study it from a mechanism design perspective and propose methods that enjoy nice theoretical guarantees and can be easily implemented in practice.

3 - Market Design for Platform-Mediated Influencer Advertising

Yan Chen, Duke University, Durham, NC, United States, Sasa Pekec

We study a centralized market design for influencer-based digital advertising, where advertisers reach users only through intermediary content creators (influencers). The presence of intermediaries introduces two challenges in valuing advertiser-influencer matches: imperfect targeting, where advertisers must target all followers of a matched influencer, and multiple coverage, where a user may be reached through multiple matched influencers. We model this as a two-stage problem: first, the platform selects a subset of influencers to participate in the market; second, advertisers are matched with participating influencers. We design a greedy approximation algorithm with a worst-case performance guarantee of $(1 - e^{-2})/2$ for this NP-hard influencer selection problem. We also provide a linear representation of the market-clearing problem, which features a non-linear concave objective due to the subadditivity of multiple coverage in targeting, and establish a sufficient condition for the existence of an integral solution. Finally, we analyze platform-controlled influencer pricing, characterizing competitive equilibrium prices and their properties. We also propose a pricing scheme that is linear in the number of followers and prove its optimality under some conditions.

4 - Landscape of Policy Optimization for Finite Horizon Mdp's with General State and Action

Minda Zhao, Georgia Institute of Technology, Atlanta, GA, United States, Xin Chen, Yifan Hu

Policy gradient methods are widely used in reinforcement learning. Yet, the nonconvexity of policy optimization imposes significant challenges in understanding the global convergence of policy gradient methods. For a class of finite-horizon Markov Decision Processes (MDPs) with general state and action spaces, we develop a framework that provides a set of easily verifiable assumptions to ensure the Polyak-Kurdyka-Łojasiewicz (PKŁ) condition of the policy optimization. Leveraging the PKŁ condition, policy gradient methods converge to the globally optimal policy with a non-asymptotic rate despite nonconvexity. Our results find applications in various control and operations models, including entropy-regularized tabular MDPs, Linear Quadratic Regulator (LQR) problems, stochastic inventory models, and stochastic cash balance problems, for which we show an ϵ -optimal policy can be obtained using a sample size in $O(\epsilon^{-1})$ and polynomial in terms of the planning horizon by stochastic policy gradient methods. Our result establishes the first sample complexity for multi-period inventory systems with Markov-modulated demands and stochastic cash balance problems in the literature.

5 - Machine Learning-Assisted Upper Confidence Bound Algorithm for Multi-Armed Bandits

Wenlong Ji, Stanford University, Stanford, CA, United States, Yihan Pan, Ruihao Zhu, Lihua Lei

Multi-armed bandit (MAB) is a prevalent paradigm for sequential decision-making under uncertainty. However, traditional bandit algorithms often face a cold-start problem, as they rely on online data that becomes available only through interaction with the environment. At the same time, decision-makers can leverage machine learning models to make predictions on the true reward. While these predictions have the potential to increase the sample size, they could be biased due to distribution shift or imprecise learning, and hence cannot fully replace the true rewards. In this paper, we explore how to utilize predictions from black-box machine learning models to improve bandit learning. We introduce the Machine Learning-Assisted Upper Confidence Bound (MLA-UCB) algorithm, which provably reduces cumulative regret by effectively de-biasing the predictions. In particular, our method is adaptive to any unknown covariance matrix between true and predicted rewards. Through extensive simulations, we show that MLA-UCB can significantly outperform the classical UCB without predictions under various settings.

1 - Expedited Service Promises: Evidence from a Food Ordering Platform with Self-Pickup

Simin Li, Tulane University, New Orleans, LA, United States, Nil Karacaoglu, Luyi Yang

Food ordering platforms increasingly enable customers to order online for self-pickup. A key challenge in this business setting is how to provide customers with estimates of the order completion time. Such service promises can not only affect customers' ordering inclination (and thus customer acquisition) but also their satisfaction after order pickup (and thus custom retention), thereby impacting business performance. This research estimates the causal effects of changing such service promises on product sales and how the effects vary by order type and product characteristics.

2 - Impact of in-Session Price Increases in the Cart on Consumer Behavior: Evidence from An Online Marketplace

Ovunc Yilmaz, University of Colorado Boulder, Boulder, CO, United States, Domenico Fabrizi, Serkan Mehder, Jiankun Sun, Zifeng Zhao

Price adjustments in the cart during shopping sessions are often a part of the customer journey on online marketplace platforms. In this research project, we investigate how customers react to in-session price increases in the cart while they are still shopping, using click-level data. We leverage a regression discontinuity design (RDD) to causally estimate the impact of these price changes on purchasing decisions.

3 - Impact of Multi-Channel Adoption on Customer Purchasing Behavior During Supply Chain Disruption

Jiachen WEI, Michigan State University, East Lansing, MI, United States, Stanley Lim, Elliot Rabinovich, Timothy Richards

This study investigates consumer purchasing behavior and inventory management challenges during pandemic-induced disruptions, using detailed sales data from a multi-channel grocery retailer. We find that although the demand surge following stay-at-home orders (SHOs) is short-lived, its impact is substantial. Consumers exhibit intense bulk-buying behavior within the first two weeks, but quickly revert to pre-pandemic patterns thereafter. Furthermore, the adoption of online channels leads to significant channel-shifting effects, with a marked decline in offline purchases during the same period.

We highlight the risks of overlooking the short-term nature of the demand spike, as doing so may result in overstocking and missed sales opportunities. To address this, we propose a transshipment policy that rebalances inventory across stores within a region. Our results underscore the importance of responsive, flexible inventory strategies

that recognize temporal demand dynamics in the face of crisis-driven shocks.

4 - Modeling and Empirical Considerations in B2b Pricing

Wen Yun, Columbia University, New York, NY, United States, Assaf Zeevi, Gal Lex

This work reports on a collaboration with a global manufacturer, Corning, with the purpose of developing a pricing decision support system for salespeople in a B2B setting. Unlike B2C settings, B2B sales involve factors not captured in historical data—such as long-term client relationships and risk management—making it infeasible for algorithms to set prices directly, as is customary in B2C settings. Instead, algorithms provide price suggestions, while salespeople retain final authority for setting transaction prices. Our work addresses two key challenges that arise in this context. First, salespeople may only partially comply with algorithmic suggestions. We model a broad class of compliance behaviors and derive a near-optimal, interpretable price recommendation policy. Second, salespeople's use of private demand information introduces unobserved confounding in demand estimation. Using real transaction data, we apply causal inference methods with instrumental variables to estimate heterogeneous treatment effects. Combining the modeling and empirical results with key considerations in human–algorithm interaction, we design a practical decision support system. Counterfactual analysis of policy performance suggests revenue gains of 1.12%–1.85% when salespeople's compliance exceeds 60% and discount rates vary within 5%.

Perspectives on Learning and Decision Making: Theory and Applications

Invited Session

Revenue Management

Chair: Wanning Chen, University of Washington, Seattle, WA, United States

1 - Emotionally-Aware Conversational Agents

Wanning Chen, University of Washington, Seattle, WA, United States, Yingfei Wang, Tongxin Zhou

We propose a novel approach for designing emotionally-aware conversational agents by integrating reinforcement learning (RL) and large language models (LLMs) within a Partially Observable Markov Decision Process (POMDP) framework. Unlike purely reactive conversational models, our chatbot dynamically tracks and anticipates latent user emotional states, strategically adapting its conversational strategies. By formulating the problem as a linear dynamical control task, we leverage Kalman filtering for state estimation and Thompson Sampling for adaptive reinforcement learning, enabling effective emotional state recovery and proactive dialogue management. Empirical evaluation demonstrates that our RL-enhanced chatbot significantly improves emotional alignment and conversational quality compared to baseline methods, closely mimicking behavior characteristics of high-quality human therapists. This forward-looking, adaptive methodology provides a theoretically grounded and practically effective framework for enhancing personalization, engagement, and emotional intelligence in AI-driven psychological counseling.

2 - Leakage-Robust Bayesian Persuasion

Mingda Qiao, MIT, Cambridge, MA, United States, Nika Haghtalab, Kunhe Yang

We introduce the concept of leakage-robust Bayesian persuasion. Situated between public persuasion and private persuasion, leakage-robust persuasion considers a setting where one or more signals privately sent by a sender to the receivers may be leaked. We study the design of leakage-robust persuasion schemes and quantify the price of robustness using two formalisms.

The first notion, k -worst-case persuasiveness, requires a scheme to remain persuasive as long as each receiver observes at most k leaked signals. We quantify the Price of Worst-case Robustness (PoWR $_k$)—the gap in sender's utility as compared to the optimal private scheme—as $\Theta(\min\{2^k, n\})$ for supermodular sender utilities and $\Theta(k)$ for submodular or XOS utilities, where n is the number of receivers. This result also establishes that in some instances, $\Theta(\log k)$ leakages are sufficient for the utility of the optimal leakage-robust persuasion to degenerate to that of public persuasion.

The second notion, expected downstream utility robustness, relaxes the persuasiveness and considers the impact on sender's utility when receivers best respond to their observations. By quantifying the Price of Downstream Robustness (PoDR) as the gap between the sender's expected utility over random leakage patterns as compared to private persuasion, we show that over several natural and structured distributions of leakage patterns, PoDR improves PoWR to $\Theta(k)$ or even $\Theta(1)$, where k is the maximum number of leaked signals observable to each receiver across leakage patterns in the distribution.

En route to these results, we introduce general-purpose algorithmic paradigms—subsampling and masking—for transforming private persuasion signaling schemes to leakage-robust ones.

3 - Uncertainty-Informed Decision Making for Intelligent Mobile Health Support

Asim Gazi, Harvard University, Cambridge, MA, United States, Bhanu Gullapalli, Daiqi Gao, Benjamin Marlin, Susan Murphy

Mobile health presents a new frontier in preventive medicine, where wireless devices are used to extend healthcare support beyond the clinic. Just-in-time adaptive interventions (JITAI) are precision mobile health systems that leverage wireless devices to estimate changes in a person's biobehavioral context and deliver timely, tailored interventions. JITAI decisions have traditionally relied on user queries (e.g., ecological momentary assessments) or reliable sensor measurements (e.g., global positioning system coordinates) to estimate changes in context, but recent advancements have leveraged machine learning-based predictions. A key challenge in doing so is that predictors are fallible, yet current JITAI learning and decision-making algorithms operate as if predictions are always perfect. Our work advances the state of the art by (1) developing methods to better quantify uncertainty in biosensor-informed predictions and (2) improving JITAI decision making with contextual bandits by leveraging measures of prediction uncertainty to improve decision making. In this talk, we will focus on our research in improving JITAI decision-making by leveraging measures of posterior prediction uncertainty. We draw inspiration from operations research, where uncertainty is fundamentally used to balance the risks of under- versus over-prediction. We demonstrate the value of our uncertainty-informed decision-making methods first in the setting of decision point scheduling for an oral health JITAI based on forecasts of user brush times. We then extend our work to the more complex setting of a contextual bandit selecting intervention actions based on predictions of biobehavioral context. We thereby demonstrate the value of uncertainty-informed decision making in improving the effectiveness of JITAI.

4 - Model-Free Meta-Bayesian Optimization via Offline Acquisition Function Learning

Alon Jacobson, Cornell University, Ithaca, NY, United States, Qian Xie, Peter Frazier

Bayesian optimization (BO) is a powerful methodology for globally optimizing expensive black-box functions, with applications ranging from hyperparameter tuning to materials design. Classical BO relies on probabilistic surrogate models, often Gaussian processes, paired with hand-crafted acquisition heuristics. However, performance can degrade when surrogate assumptions, such as smoothness or Gaussian distributions, misalign with the true objective. To address this, we propose a model-free, data-driven approach: learning acquisition functions directly from offline datasets of related optimization tasks. By formulating acquisition functions such as Expected Improvement (EI) and the Pandora's Box Gittins Index (PBGI) as loss minimizers, we train neural networks to approximate them end-to-end, without reliance on explicit surrogate models. In one-dimensional experiments, our learned acquisition functions match GP-based baselines in both optimization performance and loss, while higher-dimensional results reveal challenges of overfitting and training instability, pointing to directions for future work. This study highlights the promise of replacing hand-crafted models and heuristics in BO with learned, scalable, and domain-adaptable optimization policies.

5 - Provably Learning from Language Feedback

Wanqiao Xu, Stanford University, Stanford, CA, United States, Allen Nie, Ruijie Zheng, Aditya Modi, Adith Swaminathan, Ching-An Cheng

Interactively learning from observation and language feedback is an increasingly studied area driven by the emergence of large language model (LLM) agents. While impressive empirical demonstrations have been shown, so far a principled framing of these decision problems remains lacking.

In this work, we formalize the Learning from Language Feedback (LLF) problem, assert sufficient assumptions to enable learning despite latent rewards, and introduce transfer eluder dimension as a complexity measure to characterize the hardness of LLF problems. We show that transfer eluder dimension captures the intuition that information in the feedback changes the learning complexity of the LLF problem. We demonstrate cases where learning from rich language feedback can be exponentially faster than learning from reward. We develop a no-regret algorithm, called LLF-UCB, that provably solves LLF problems through sequential interactions, with performance guarantees that scale with the transfer eluder dimension of the problem. Our contributions mark a first step towards designing principled interactive learning algorithms from generic language feedback.

Temporary Abstract

3 - Dynamic Learning for Joint Pricing, Advertising, and Inventory Management

Huseyin Gurkan, ESMT GmbH, Berlin, Germany, Bora Keskin, Rodney Parker

Startup firms often lack distinct functional departments like marketing and operations, making cross-functional decisions difficult. These interdependent choices are further complicated by the absence of historical customer data. Consequently, startups must simultaneously learn about customer preferences while making marketing (pricing and advertising) and operational (inventory) decisions. This paper studies a setting where a firm jointly determines pricing, inventory, and advertising over TT periods while learning about demand and advertising response models. We characterize sufficient conditions under which cross-functional decisions enable exponentially fast learning rates. Based on these conditions, we propose an easy-to-implement policy that is asymptotically optimal: its profit gap relative to a clairvoyant with perfect information grows only at order $\log T$. Numerical experiments show that jointly learning about advertising and demand models is critical for strong profit performance. Our findings highlight the importance of integrating marketing and operational decisions to improve business outcomes. The learning conditions we identify emphasize how the connections between these decisions are key to understanding consumer behavior. Moreover, numerical results show that avoiding experimentation to preserve short-term profits leads to significantly worse long-term performance. Overall, our integrated approach offers practical guidance for entrepreneurs and managers aiming for better resource allocation, improved customer insights, and enhanced profitability.

4 - Mechanism Design with Post-Allocation Inspection and Exclusion Penalties

Xuanjie Li, Duke University, Durham, NC, United States

We study repeated interactions between a seller and a buyer in settings where the seller can inspect the buyer's private type and potentially exclude the buyer from future rounds upon detecting misreporting. This additional "exclusion penalty" instrument can take different forms, such as deterministic or probabilistic inspection and exclusion, and leads to novel mechanism design challenges. We develop a unifying framework to study these forms of inspection and exclusion penalty, characterize optimal mechanisms, and provide a dynamic programming solution to implement the optimal mechanism in multiple rounds. Our results show how inspection capabilities, when paired with strategic exclusion decisions, can augment classical mechanism design, offer new levers to align incentives and improve revenues.

5 - Optimality of Public Persuasion for Single-Good Allocation

Chen Chen, New York University Shanghai, Shanghai, China, People's Republic of, Xuyuanda Qi

We study an information design problem in which a sender seeks to allocate an indivisible good to n receivers by strategically disclosing information. The good can be allocated to at most one receiver, and each strategic receiver decides whether to accept based on self-interest. Relevant applications include school advisors promoting students for job placements and incubators introducing startups to potential investors. The sender can either send different signals to different receivers (i.e., *private persuasion*) or broadcast the same signal to all receivers (i.e., *public persuasion*). After receiving signals, receivers may communicate with each other in their self-interest to further reduce uncertainty about the good. We demonstrate when the sender has a known preference among the receivers, public persuasion is optimal, regardless of how receivers communicate. The optimal public persuasion can be derived from a first-best relaxation problem that imposes only the receivers' participation constraints. We then focus on a special case where the good's characteristics are captured by a one-dimensional variable, and receivers' utility functions are linear in this variable. Using a dual approach, we derive optimality conditions for persuasion mechanisms. This leads to closed-form optimal mechanisms for the two-receiver case and an explicit characterization of the set of optimal mechanisms in the general case, thereby enhancing our understanding of their structural properties.

1 - Optimizing the Deployment of Defibrillators

Timothy Chan, University of Toronto, Toronto, ON, Canada

This talk discusses several projects on optimizing the deployment of defibrillators for cardiac arrest, including placement of static defibrillators and drone delivery. Practical impact will be presented along with a discussion of how these projects have opened new doors to other research topics.

2 - Shaping Health Policy with Operations Research: The Hepatitis C Experience

Jagpreet Chhatwal, Harvard Medical School, Mass General Hospital, Boston, MA, United States

Over the past 12 years, Jagpreet Chhatwal and his team have developed a suite of mathematical models and decision tools that have directly informed hepatitis C elimination strategies. These models have been used by the White House, the Centers for Disease Control and Prevention, and the World Health Organization to guide

national and global health policies. In this talk, Dr. Chhatwal will highlight how these models shaped real-world decisions and the lessons learned from collaborations with policymakers. He will also discuss strategies for building successful partnerships and ensuring that operations research reach the stakeholders who need them most. The session will provide practical insights for the INFORMS community on how to maximize the real-world impact and visibility of their research.

1 - Technological Modularity in Resource Redeployment

Yi Luo, IE Business School , Madrid , Spain

This paper aims to examine how technological modularity can affect resource redeployability. Building on real options theory, we argue that technological modularity can simultaneously enhance inducements to redeploy capacity-constrained resources when volatility reveals superior uses, and lower the internal adjustment costs in the redeployment process. This dual mechanism suggests that technological modularity will amplify the positive relationship between volatility and firm market value identified in prior work on resource redeployment. To test our hypotheses, we use cross-sectional Fama-MacBeth regression with a patent-based measure on a panel of U.S. public firms. By integrating the literature on modularity and resource redeployment, this study endogenizes inducements and costs of redeploying resources, demonstrating that the technology architecture plays an important role in redeploying resources internally, and that technological modularity is a critical boundary condition for the market valuation of flexibility.

2 - A Research Study of Optimized Vehicle Design Space Exploration Using Multiple Criteria Decision Making

KyongRyol Yoon, Hyundai Motors, Seoul, Korea, Republic of, Mauro Munerato

Recent vehicle development is highly dependent on data-driven decision making with categorized target and value in earlier step. This means that a vehicle should satisfy purpose-based performance goal, reliable battery safety and competitive low TCO. However in vehicle concept design development, this strategy could be difficult choice because of getting less data and unreasonable result prediction. To solve this problem, several Automotive OEM has researched and developed an exploration space analysis methodology. It was valuable approach but another issue was upcoming, a lot of concept design candidate were an obstacle of right decision making. In this study, Multiple Criteria Decision Making was introduced and researched in order to get an efficient exploration and optimum design. The result was shown that ranking and sorting MCDM algorithm with real-time weighting could be the key player in initial vehicle development.

3 - Capability OR Liability? the Role of Innovativeness Under Government Sanctions

Zhihong TIAN, The Hong Kong Polytechnic University, Hong Kong, China, People's Republic of, Di Fan, Chengyong Xiao

Previous literature widely regards firm innovativeness crucial for building a capability for coping with environmental uncertainties. However, it remains unclear whether innovativeness remains beneficial under increasingly prevalent geopolitical risks, such as foreign government sanctions targeting specific firms. Drawing on an integrated framework between Resource Dependence Theory and the Core Rigidity perspective, we conceptualize sanctions as disruptions that constrain targeted firms' access to critical external resources, including supply chains, technology, and markets. Given innovative firms' heightened reliance on specialized external inputs and established routines, we argue that innovativeness may paradoxically undermine the firm's responsiveness and increase vulnerability during sanctions. Using a sample of 101 Chinese listed firms included in the sanction list issued by the US International Trade Administration of the Department of Commerce, our difference-in-difference analysis finds that sanctions undermine the inventory and profitability performance of these firms. Furthermore, we find that firms with high-quality (indicated by patent citations) and broader (indicated by the scope of patents) innovation suffer more from the sanctions. These results demonstrate that the sanctions effectively cut off the supply chain support necessary for innovation. Our findings suggest that without supply chain backing, innovativeness's resilience against sanctions proves to be a fragile facade. We discuss the contributions to operations and supply chain management literature in the areas of innovation and public policy, and provide managerial and policy implications.

4 - Flexible vs. Dedicated Technology Choice in the Presence of Multiproduct Subscription Programs

Liling LU, Singapore Management University, Singapore, Singapore

In recent years, automotive manufacturers have started offering multi-car subscription programs that give customers access to a menu of car models in a certain fleet with possibility of switching from one model to another for an all-inclusive fee. The fleet's maintenance and depreciation costs during the program are borne by the manufacturers before these cars are sold in the preowned market. This paper studies how offering such a subscription program shapes the firm's flexible versus dedicated technology choice and capacity investment decisions. We consider a two-product firm that makes these decisions under uncertain demand in a single subscription period. The firm faces two types of subscription demand based on which product is requested at the beginning of the period. Halfway through the period, a proportion of the existing customers returns their allocated product and requests switching to the other product. The firm incurs a cost unless this request is satisfied by the existing fleet of products. In deciding the manufacturing volume the firm considers not only the realized demand but also the future switching requests where some products can be reserved to satisfy these requests. We characterize the firm's optimal decisions and examine, both analytically and numerically using experiments calibrated to data, how demand correlation shapes the firm's profitability with each technology as well as the optimal technology choice. We demonstrate that our findings can be significantly different from those in the traditional setting (where the firm sells its products) and we explain why.

5 - Minimizing Energy Consumption of a Robotic Arms by Considering Base and Idle Positions in Automated Warehouses

Seung Hyeon Eom, Kyung Hee University, Yongin-si, Korea, Republic of, Byung hun Song, Hyun Woo Jeon, Jin Goo Jeong

The rise of e-commerce has accelerated the deployment of warehouses supported by robotic arms, leading to increased energy consumption. In response, this study develops a model to estimate and minimize the energy consumption of robotic arms based on their operational movements within automated warehouse systems. Two key decision variables—the base position (BP) and the idle position (IP)—are determined to minimize energy usage. These variables are influenced by operational factors such as idle time, payload, and positional error. Using an L9 orthogonal experimental design, simulation experiments validate the significant impact of these factors on the robotic arms' energy consumption and optimal positioning. To guarantee the uniqueness of the global optimum, energy consumption is mathematically formulated as a strictly convex function with respect to BP. The simulation experiment results indicate that as the position error of objects on the conveyor belt increases, the impact of BP and IP control becomes more significant. The proposed energy estimation and optimization model contributes significantly to operational cost reduction and sustainability in automated warehouse environments.

6 - Automation in Part Number Stamping Operations: A Case Study

Junayed Pasha, Gannon University, Erie, PA, United States, Daniel Rutkowski, Jayed Pasha, Madalyn Myers, Andrea Martinez Ortuno

A stamping and inspection process is a critical step in various manufacturing lines, where parts are marked with identification numbers, checked for quality, and either passed to the next production stage or scrapped due to non-conformance. This research presents a comprehensive simulation modeling and analysis of this critical step, comparing manual and automated operations. A simulation model is developed under this study that replicates the flow of parts through the system, capturing key performance metrics, such as throughput, error rates, and cycle times. By creating digital twins of both the manual and automated versions of this processing step, the impact of automation on the overall system performance is quantified. A number of scenarios are explored in order to account for variability in part arrival rates, processing times, and defect occurrences. Simulation results indicate that automation significantly improves process reliability and throughput, with a significant increase in the number of successful parts processed per hour. Additionally, the automated system demonstrates a significant reduction in quality-related scrap rates. These

improvements have cascading effects on adjacent processing steps, increasing overall line efficiency by a significant amount. Hence, the insights gained from this research could guide manufacturers in making data-driven decisions about process automation and resource allocation.

1 - Customizing Follow-up of Cancer Patients: Case of Breast Cancer in Morocco

Abdelaziz Berrado, EMI, Mohammed V University in Rabat, Rabat, Morocco, Loubna Benabbou

This ongoing research work, which involves artificial intelligence experts and medical oncologists is about the development of an intelligent system for a predictive prognosis and a personalized surveillance/follow-up of breast cancer patients. The system would save lives, lower the cost of treatment and follow-up and relieve the capacity of the oncology treatment centers for better management of new and old cases of breast cancer.

The targeted intelligent decision support system will guide the practitioner in the surveillance of patients with breast cancer based on the risk of relapse specific to each patient. It will enable the oncologist or general practitioner to introduce several attributes relative to the patient's history and condition, and in return obtain a personalized proposal for a follow-up plan for the patient, depending on the risk of relapse and the history of the patient. Follow-ups will vary in rhythm/frequency and also in tests to be prescribed.

The resulting system will, make it possible to optimize the surveillance of former patients and to propose a personalized monitoring plan instead of a systematic monitoring frequency as recommended by the current guidelines (every three months) . This will help avoid inappropriate monitoring that is either too heavy or too light and will allow better management of hospital capacity. Furthermore, a better prediction of the risk of relapse will make it possible to intervene more quickly for cases at high risk of relapse. The system will make it possible to delegate the surveillance task to non-specialist doctors.

2 - Gatekeepers' Competition and Optimal Payment Scheme in Healthcare

Ji-Su Lee, KAIST, Daejeon, Korea, Republic of, Woonam Hwang, Taesik Lee

This study investigates how different payment schemes influence the healthcare quality and referral decisions of lower-level hospitals operating as gatekeepers in hierarchical healthcare systems. We develop analytical models to examine how market structure—monopoly versus duopoly—and the intensity of competition affect the ability of payment mechanisms to align hospital behavior with socially optimal outcomes. We analyze several payment schemes, including fee-for-service, fund-holding gatekeeper, and outcome-based penalty models, and propose a novel referral threshold-based subsidy scheme. Our findings reveal that conventional fee-for-service schemes generally fail to achieve the social optimum due to their limited incentive alignment. In monopolistic markets, outcome-based penalties effectively induce optimal hospital behavior. In duopolistic settings, the effectiveness of payment schemes critically depends on competition intensity. Under moderate competition, multiple schemes can achieve optimal outcomes, though with varying cost implications for payers and profit outcomes for providers. However, when competition is intense, only the proposed referral threshold-based subsidies can restore socially optimal outcomes. This research offers actionable insights for policymakers seeking to design payment schemes that enhance the performance of gatekeeper-based healthcare systems by accounting for competitive dynamics and market structure.

3 - A Stochastic Optimization Framework for Prioritizing SDOH Documentation for Chronic Disease Patients

Ifeoluwa Solaru, Louisiana State University, Baton Rouge, LA, United States, Laura Ikuma

This study develops a stochastic optimization framework to tackle the operational challenges of social determinants of health (SDOH) documentation in resource-constrained healthcare systems using 49,492 chronic patient records from a Louisiana medical center between January and December 2024. The study formulates a chance-constrained programming model that maximizes expected clinical impact, quantified through effect sizes - Cramer's V and Phi ($\Phi=0.16$ for alcohol use, $\Phi=0.073$ for housing instability) - while probabilistically bounding documentation uncertainty across 12 social needs. The model incorporates a greedy ϵ -approximation algorithm that ranks needs by risk-adjusted yield ($\Phi / (\text{unknown rate} + \epsilon)$), identifying alcohol use (priority score = 0.625), housing instability (0.110), and social connection (0.093) as the highest screening priorities. Probabilistic constraints derived from refusal patterns (ranging from 89% decline for physical activity to 26% for alcohol use) and Monte Carlo validation demonstrate that the stability of the screening priorities is sustained under parameter uncertainty and varying response completeness. The framework requires only three inputs per social need -clinical effect size (Φ), documentation completeness ($1 - \text{unknown rate}$), and refusal probability, making it computationally tractable and highly adaptable. Sensitivity analysis indicates that the model remains robust to $\pm 15\%$ variation in effect sizes (95% CI) and maintains feasibility even when unknown response rates exceed 80%. This prioritization approach offers a reproducible, data-driven strategy to guide SDOH screening efforts, aligning limited clinical resources with population-level risk impact while accounting for real-world documentation limitations.

4 - Chronic Risk & Structural Shield: Diabetes, Income, and Cancer Outcomes in the United States

Deepthi Singh, California State University - Long Beach, Long Beach, CA, United States, Banafsheh Behzad

Cancer is a leading global cause of death, with incidence projected to rise by 70% in the coming decades. Modifiable risk factors—such as diabetes, obesity, tobacco, and alcohol use—contribute to nearly half of all cancer cases. Our study focuses on the role of diabetes in cancer outcomes and how income and health coverage influence this relationship. Using panel data from 50 U.S. states and the District of Columbia from 1997 to 2019, we estimate dynamic panel models via system Generalized Method of Moments (GMM). We combine internal lag instruments with external policy shocks to address endogeneity. States are grouped into three clusters by lifestyle patterns to examine heterogeneity. Our results indicate diabetes as a strong, consistent predictor of both cancer incidence and mortality. Its impact is significantly moderated by income, with higher income reducing diabetes-related cancer risk. We find that health coverage is positively associated with cancer incidence, likely reflecting increased detection, but it does not consistently reduce mortality. Cluster-specific results show that the income-buffering effect is strongest in states with low-risk lifestyles and higher coverage. The effect of diabetes on cancer is substantial and shaped by socioeconomic context. Income and access play critical roles in moderating this risk. These results underscore the importance of prioritizing income-sensitive, chronic disease-focused interventions, particularly in high-risk and underserved states, to reduce the cancer burden linked to diabetes.

5 - Variational Inference Federated Learning for Incomplete Multi-Modality Imaging on Alzheimer's Disease Prediction

Zhiyang Zheng, Georgia Institute of Technology, Atlanta, GA, United States, Ruiqi Chen, Yi Su, Kewei Chen, David Weidman, Teresa Wu, Shih-Chung Lo, Fleming Lure, Jing Li

Alzheimer's Disease (AD) is a devastating neurodegenerative disease, often preceded by Mild Cognitive Impairment (MCI), making the early prediction of MCI conversion to AD critical for timely intervention. While multi-modality neuroimaging enhances predictive accuracy, its widespread application in machine learning (ML) models is hampered by incomplete datasets across medical sites and significant privacy barriers to data sharing. Current federated learning (FL) solutions in neuroimaging typically focus on single-modality data, thereby missing the synergistic advantages of multi-modal approaches. This paper introduces FedVICML (Federated Variational Inference for Cross-Modality Learning), a novel FL framework specifically designed to tackle these challenges by enabling sites with varying access to imaging modalities to collaboratively train models without centralized data sharing, thus preserving patient privacy. FedVICML uniquely integrates FL with a novel cross-model variational inference methodology, employing two distinct Bayesian neural networks (one for multi-modal and another for single-modal data), and an extended variational inference-based mechanism to facilitate knowledge transfer between these models. The FedVICML framework provides a decentralized, privacy-preserving learning with incomplete multi-modality data by innovatively integrating FL and cross-model variational inference. We demonstrated its efficacy by applying the proposed framework to

simulated data and real-world data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) for predicting MCI to AD progression; FedVICML achieved notable gains in prediction performance compared to isolated FL baselines, underscoring its potential for robust, collaborative medical research under heterogeneous data conditions.

6 - Caim-Oird Risk Tool: Enhancing Clinician-Ai-Interaction to Monitor Opioid-Induced Respiratory Depression in Surgery and Trauma Patients Using a Multi-Level Interpretability Approach

Elham Nasarian, Virginia Tech, Blacksburg, VA, United States, Huaiyang Zhong, Kwok-Leung Tsui

Opioid therapy is commonly used for postoperative pain management but carries significant risks, particularly opioid-induced respiratory depression (OIRD), which is associated with increased mortality, longer hospital stays, and higher healthcare costs. Despite its prevalence, OIRD remains unrecognizable. This study compares the PRODIGY score with our own risk prediction model using interpretable ML techniques to identify key predictors of OIRD. The Random Forest model outperformed others in recall and precision, suggesting its potential for integration into clinical decision support systems (CDSS). Additionally, we developed a new risk score tool based on the most important factors identified. Our findings emphasize the need for better predictive tools, continuous monitoring, and timely interventions to reduce the clinical and economic burden of OIRD.

7 - Synthetic - Empirical Log Fusion for Deep Learning Prediction of Outpatient Queue Dynamics

Daesan Park, Pusan National University, Busan, Korea, Republic of, Dohee Kim, Hyerim Bae

Classical queueing formulas provide closed-form steady-state metrics and clear managerial insights into system sensitivity under stable loads; however, their analytical reach diminishes when demand spikes or service rules change. Discrete-event simulation (DES) accurately reproduces such dynamics, but repeated runs and calibration hinder real-time use. Recent deep learning predictors enhance speed, but most are trained only on synthetic DES episodes—introducing model bias—or solely on sparse field logs, which leaves them insufficiently exposed to rare transients and measurement noise.

To address these limitations, we propose a data fusion framework that provides an off-the-shelf deep learning predictor with both synthetic and empirical samples. A configurable simulator generates both routine and stress scenarios. Each episode delivers queue length paths and moments of waiting time, while the clinic logs contribute the same indicators under routine conditions. Within this framework, we systematically adjust the ratio of synthetic to empirical data to train the predictor and analyze how this ratio balances steady-state accuracy against responsiveness under stress. The proposed framework is validated using outpatient clinic data to demonstrate its practical applicability while still offering rapid inference for operational decision support.

Results demonstrate (i) how prediction error varies with log share across routine and stress conditions, (ii) that fusion training remains resilient to measurement noise and log sparsity, and (iii) offers practical guidance for selecting simulation-to-log ratios—uniting the strengths of analytic formulas, simulation, and deep learning.

8 - Nonlinear Risk Mapping and Conformal Confidence Intervals for Accurate Dr Prediction

Mahyar Mahmoudi, Oklahoma State University, Stillwater, OK, United States, Tieming Liu

Diabetic retinopathy (DR) remains a leading cause of vision loss worldwide, particularly among individuals with long-standing diabetes. This study introduces a novel framework to construct a clinically interpretable and computationally efficient risk index for early detection of DR using electronic health records. We selected ten essential predictors through a robust ensemble feature selection approach using gradient boosting, achieving a compact yet powerful predictive model. To discretize continuous features, we adopted a decision-tree-based method to determine optimal bin cutoffs, improving granularity and interpretability in clinical settings.

Unlike prior linear risk scoring methods, we contributed a nonlinear transformation to calculate risk scores, enabling more realistic risk weighting across variable ranges. Additionally, we applied conformal prediction to estimate confidence intervals for every possible total risk score, offering a robust alternative to traditional statistical approaches such as Wilson's method.

Our risk index model demonstrated strong performance with an AUC of 0.89 on the internal validation cohort and 0.83 on an external validation cohort, confirming its generalizability across independent populations. The model provides both probability scores and uncertainty bounds, supporting confident decision-making in DR screening initiatives.

This work advances the methodological foundation for risk score generation in chronic disease management, particularly in under-resourced environments where interpretability, ease of use, and confidence quantification are critical. Our approach bridges the gap between complex machine learning models and actionable clinical tools for proactive DR management.

1 - On the Complexity of Causal Invariant Learning Under Distribution Shift

Haotian Xie, Ohio State University, Columbus, OH, United States, Simon Zhang, Kun Jin, Cathy Xia

Out-of-distribution (OoD) generalization remains a fundamental challenge in supervised machine learning. Models often fail when applied to data that differ from the training distribution. Traditional methods, which rely heavily on statistical correlations, are particularly vulnerable to such distributional shifts.

Causal AI offers a principled alternative by modeling the underlying cause-and-effect relationships in data using causal graphs. This talk focuses on causal invariant learning: a family of approaches that seek to uncover stable, causally relevant features by learning *invariant representations* that disentangle true causal structure from spurious correlations. These representations aim to remain predictive under both environmental interventions and distributional changes.

We will review key algorithmic strategies, including Invariant Risk Minimization (IRM), Variance Risk Extrapolation (V-REx), and other causally motivated objectives. While these methods show promising empirical results, a comprehensive theoretical understanding is still emerging.

In this talk, we explore the conditions under which causal invariant learning can succeed, and present preliminary results on its computational complexity and generalization guarantees. Our aim is to illuminate both the practical potential and theoretical boundaries of causal methods for robust machine learning in the face of distribution shift.

2 - Navigating Content Strategy in the Face of Platform Moderation: the Case of Youtube's Borderline Policy

Shervin Shahrokhi Tehrani, University of Texas at Dallas, Dallas, TX, United States, Reza Roshangarzadeh

Social media platforms like YouTube rely on algorithmic moderation to manage harmful content, often demoting so-called borderline content—material that skirts but does not explicitly violate platform guidelines. This study investigates how content creators dynamically adjust their strategies under such moderation uncertainty. Using a curated dataset of over 3,800 videos across sensitive topics—including election integrity, COVID-19, and the Ukraine war—we construct a borderline index by applying

Natural Language Inference (NLI) to quantify each video's alignment with known misinformation. We model creators' topic choices as a dynamic Bayesian learning process, where engagement outcomes act as noisy signals reflecting the platform's treatment of borderline content. Empirical results show that creators initially overestimate the engagement potential of borderline topics but recalibrate expectations downward with experience. We also document substantial spillover learning: creators revise beliefs about related, untested topics based on observed engagement shifts. Counterfactual simulations indicate that stricter moderation signals reduce borderline content prevalence and boost overall platform engagement. These findings shed light on how creators navigate opaque moderation environments and offer actionable insights for platform governance and content strategy. Our framework emphasizes the role of dynamic adaptation in content ecosystems and highlights how moderation policies can shape both content and engagement outcomes.

3 - Rs-Ort: a Reduced-Space Branch-and-Bound Algorithm for Optimal Regression Trees

Cristobal Heredia Galleguillos, University of South Florida, Tampa, FL, United States, Pedro Chumplitaz, Kaixun Hua

Mixed-integer programming (MIP) has emerged as a powerful framework for learning optimal decision trees. Yet, existing MIP approaches for regression tasks are either limited to purely binary features or become computationally intractable when continuous, large-scale data are involved. Naively binarizing continuous features sacrifices global optimality and often yields needlessly deep trees. We recast the optimal regression-tree training as a two-stage optimisation problem and propose Reduced-Space Optimal Regression Trees (RS-ORT)—a specialised branch-and-bound (BB) algorithm that branches exclusively on tree-structural variables. This design guarantees the algorithm's convergence and its independence from the number of training samples. Leveraging the model's structure, we introduce several tightening techniques—closed-form leaf prediction, empirical threshold discretisation, and exact depth-1 subtree parsing—that combine with decomposable upper and lower bounding strategies to accelerate the training. The BB node-wise decomposition further enables trivial parallel execution, further alleviating the computational intractability even for million-size datasets. On 11 UCI regression benchmarks containing both binary and continuous features, RS-ORT generally delivers lower training loss and superior test performance than state-of-the-art methods. Notably, on datasets with up to 2000000 samples with continuous features, RS-ORT can obtain competitive training performance with a simpler tree structure and provable optimality in four hours.

4 - Multimodal Personalized Federated Learning for Product Recommendation in Fast Fashion

Xinhui Yu, The University of British Columbia, Vancouver, BC, Canada, Sophie Liu, Chunhua Wu

Recommendation systems play a pivotal role in modern marketing and e-commerce, enabling businesses to personalize customer experiences, optimize product exposure, and enhance engagement and conversions. Building effective recommendation systems is particularly critical in dynamic, data-sensitive domains such as fast fashion.

We introduce pFedMMRec, a personalized federated learning framework for fast fashion product recommendation. Unlike conventional federated recommendation approaches that rely predominantly on item ID embeddings and often overlook rich multimodal data that influences purchasing decisions, pFedMMRec employs a novel dual-branch architecture. This structure separately models each customer's design preference and price sensitivity by leveraging multimodal product data, including images, text descriptions, and price information. To enhance the model's discriminative capabilities, we introduce a threshold-based regularization loss that creates greater separation between each customer's preferred and non-preferred design elements. Additionally, we develop personalized adapters for image and text processing that enable the model to learn customer-specific item representations while effectively leveraging collective knowledge across the federated network.

We validate our methodology through comprehensive simulation experiments conducted on four diverse clothing datasets spanning different product categories (long sleeves, pants, dresses, and outerwear) extracted from real-world fast fashion data. Experimental results demonstrate that pFedMMRec consistently outperforms existing methods, confirming the effectiveness of our multimodal, privacy-preserving, personalized approach in addressing the challenges of both limited information exploration and data heterogeneity in federated fashion recommendation systems.

This research contributes to the intersection of recommendation systems, marketing analytics, and federated learning by offering a scalable solution for adaptive, secure, personalized product recommendations in fast-paced retail environments.

5 - Managing the Learning-Retention Trade-off: a Field Experiment on Incentivizing Educational Content in a Video Game

Alexander Jensen, Kellogg School of Management, Northwestern University, Evanston, IL, United States, Sebastien Martin, Karen Smilowitz

The integration of educational content into digital environments presents a fundamental trade-off between promoting learning and sustaining user engagement. Although educational technology has been studied extensively, educational video games, particularly those blending structured learning with open-ended play, remain underexplored in the operations management literature. Using gameplay data from a video game designed for children aged 5–12, we analyze how players alternate between “work” (educational content) and “play” (exploration, quests, and combat). We observe that user retention declines sharply after initial exposure to educational content and that early educational engagement is strongly correlated with permanent user exit. While these patterns are not necessarily causal, they highlight a critical behavioral tension in game design that is also applicable in broader educational settings. To address this, we are conducting a randomized controlled trial (June 2025) to test whether in-game notifications, delivered at different points during a session, can increase educational engagement without reducing retention.

6 - Optimization of Insulin Pump Infusion Rate by Reinforcement Learning

Jinkun Lee, East Carolina University, Greenville, NC, United States

Minimizing insulin dosage while effectively controlling plasma glucose concentrations is crucial for reducing the risk of insulin resistance and ensuring effective long-term diabetes management. We focus on designing an insulin pump infusion controller modeled by a system of ordinary differential equations that captures the dynamic interaction between glucose and insulin in the human body. The primary objective is to maintain plasma glucose levels within a healthy range over time. To achieve this, we employ Reinforcement Learning (RL) and investigate the structure of a weighted reward function to evaluate RL's ability to discover an optimal infusion strategy that meets predefined clinical targets. The RL-generated insulin infusion profiles will be compared to those derived from a Proportional-Integral-Derivative (PID) controller and current best practices. This comparison will be conducted by analyzing the area under the glucose concentration curve for each approach, to assess the suitability of RL for this application.

1 - Mobile Condition-Based Maintenance with Heterogeneous Repair Types and Durations

Emma Gibbs, University of Pittsburgh, Pittsburgh, PA, United States, Lisa Maillart, Oleg Prokopyev

This work considers the problem of performing condition-based maintenance on a set of geographically distributed assets via a single mobile maintenance resource. By formulating a Markov decision process (MDP), optimal timing and selection of positioning and repair decisions are determined dynamically as a function of asset health and maintenance resource location to minimize total downtime, travel, and maintenance expenses. As an extension of the previous work, assets may have heterogeneous non-unit repair durations, and maintenance resource has access to multiple repair actions. These generalizations facilitate the examination of how asset repair durations impact preventive maintenance of nearby assets, repositioning, idling in anticipation of asset deterioration, and tradeoffs between short-but-costly or long-but-inexpensive repairs. Optimal policies for the MDP are explored analytically and numerically with respect to graph structure and repair durations.

2 - Condition-Based Production for Stochastically Deteriorating Systems

Collin Drent, Eindhoven University of Technology, Eindhoven, Netherlands, Melvin Drent, Joachim Arts

Production systems degrade stochastically with use and may ultimately fail, incurring significant costs during scheduled maintenance. This degradation is generally influenced by the system's production rate: Higher production yields more revenue but also accelerates wear. As a result, production should be dynamically adjusted to balance revenue generation and system degradation between maintenance moments. In this context, we study a two-level decision-making problem. At the operational level, we investigate how to optimally control production to manage degradation between planned maintenance moments. At the tactical level, we study when to schedule these maintenance moments, assuming optimal operational control in between. We cast the operational problem as a continuous-time Markov decision process, and we prove that the optimal policy exhibits intuitive monotonic properties. We also provide sufficient conditions under which so-called bang-bang production policies, where production switches between extremes, are optimal. For the tactical problem, we identify a structural property that simplifies its optimization considerably. Numerical experiments show that our approach outperforms existing state-of-the-art methods in realistic scenarios.

3 - Optimal Replacement of Fixed-Base and Floating Offshore Wind Turbines

Morteza Soltani, Clemson University, Clemson, SC, United States, Jeffrey Kharoufeh, Amin Khademi

Floating offshore wind (FOW) turbines have emerged as a promising solution for harnessing wind energy in deep ocean waters where fixed-base turbines are infeasible. However, replacement of major components is a challenging challenge due to harsh environmental conditions and limited availability of specialized resources, such as jack-up vessels (JUVs). Unlike fixed-base turbines, FOW turbines can be towed to either shallow waters or shore for replacement activities. We present a framework for optimizing replacement decisions for both fixed-base and FOW turbines under stochastic environmental conditions. The environment states in shallow and deep waters are modeled as a bivariate Markov chain that exhibits (weak) positive correlation at each time step. A Markov decision process (MDP) model is created to jointly optimize replacement and JUV requesting decisions over an infinite planning horizon. The model incorporates stochastic dependence arising from degradation processes influenced by correlated environment states, and economic dependence due to sharing of a JUV across turbine types. We characterize the structural properties of the optimal policies and show that both replacement and JUV requesting decisions exhibit threshold behavior with respect to turbine degradation. Finally, we provide sufficient conditions under which these policies are monotone in the environmental state.

4 - Towards Foundational Models for Diagnostics and Optimization in Energy Systems

Murat Yildirim, Wayne State University, Detroit, MI, United States, MOHAMMAD BADFAR, Iman Kazemian, Paritosh Ramanan, Ratna Chinnam

Modern data-driven systems face two central challenges: the complexity of data engineering and its connection to decision-making. In this work, we present two complementary frameworks that address these bottlenecks—ADEPT and ATOM—each targeting automation and scalability in predictive analytics and constrained optimization. ADEPT (Automated Data Engineering Pipeline via Text Embeddings) eliminates the need for traditional feature engineering by converting raw multivariate time series into text-based representations and processing them through a variational bottleneck over pretrained embeddings. This approach offers resilience to missing values, irregular timestamps, and corrupted records, and enables end-to-end prediction pipelines with minimal manual intervention. Experiments in a hydropower dataset demonstrate ADEPT's consistent outperformance over conventional methods. In parallel, ATOM (Attention-based Time-series Optimization Model) offers a paradigm shift for condition-based maintenance by directly learning decision policies from raw sensor streams—circumventing the typical two-stage predict-then-optimize paradigm. ATOM integrates operational constraints, such as resource limits and crew schedules, through attention-masking, producing interpretable, cost-efficient maintenance policies. On commercial Li-ion battery fleets, ATOM achieves up to 35% cost savings over standard baselines, while demonstrating early-stage foundation model capabilities through transferability across cost regimes. Together, ADEPT and ATOM form an integrated vision for the future of automated, constraint-aware decision systems: one that fuses representation learning with decision-making and removes the traditional divide between data preparation and optimization.

5 - A Stochastic Optimization Framework to Integrate Turbine Failure Risks and Accessibility Forecasts to Offshore Wind Farm Operations, Maintenance, and Logistics

Muhammet Ceyhan Sahin, Wayne State University, Detroit, MI, United States, Feng Ye, Ahmed Aziz Ezzat, Onur Kilic, Murat Yildirim

This paper introduces ALBATROS (accessibility-aware logistics based approach for turbine reliability and operations under stochasticity), a novel optimization framework for coordinating operations, maintenance, and vessel logistics in offshore wind (OSW) farms. ALBATROS captures key sources of uncertainty through (i) sensor-driven prognostic models for turbine degradation and failure risks, (ii) data-driven met-ocean forecasts of wind and wave conditions for accessibility, (iii) stochastic modeling of electricity prices and wind-dependent power production, and (iv) detailed vessel routing and logistics for geographically dispersed farms. These components are unified in a two-stage stochastic mixed-integer model that jointly optimizes condition-based maintenance, vessel routing, and production planning. The model operates in a receding horizon fashion to coordinate hourly and daily decisions over a 60-day planning window. A comprehensive computational study involving 100 turbines across four OSW locations benchmarks ALBATROS against conventional practices. Results show significant improvements in cost reduction, turbine uptime, and system reliability. The study also quantifies the value of sensor-driven condition monitoring over periodic maintenance, demonstrates the role of accessibility forecasting in improving scheduling feasibility, and evaluates the impact of vessel availability windows. By integrating real-world data, forecasting, and logistics in a unified decision-making framework, ALBATROS provides a robust, data-driven solution for OSW O&M planning under uncertainty.

Tensor-based Modeling and Control for Digital Manufacturing

Invited Session

Quality, Statistics and Reliability

Chair: Jianjun Shi, ISyE Georgia Tech, Atlanta, GA, United States

Co-Chair: Zihan Zhang, Georgia Institute of Technology, Atlanta, GA, United States

1 - Nonlinear Spatio-Temporal Run-to-Run Control: Leveraging Diffusion Models for Disturbance Management

Jianjun Shi, ISyE Georgia Tech, Atlanta, GA, United States

Run-to-run (R2R) control is widely used in advanced manufacturing processes. Conventional R2R control methods often assume that system disturbances exhibit linear structures or low-rank approximations in high-dimensional data, such as images or videos. While these assumptions facilitate implementation, they limit the effectiveness of R2R control in managing sophisticated manufacturing processes with intricate nonlinear disturbances. To address these challenges, we propose a novel nonlinear spatio-temporal R2R control framework that estimates system disturbances using a diffusion model and applies control actions to compensate for them. The proposed approach integrates an offline modeling phase to capture disturbance dynamics and an online control phase that dynamically adjusts actions to minimize deviations from the target system response, ensuring system stability and precision. Unlike conventional deterministic control strategies, the proposed method explicitly quantifies uncertainty, enabling more robust and informed decision-making. The effectiveness of this method is validated through simulation studies and a case study, demonstrating its adaptability in complex, high-dimensional environments.

2 - On Model Compression for Neural Networks: Framework, Algorithm, and Convergence Guarantee

Bo Shen, New Jersey Institute of Technology, Newark, NJ, United States, Chenyang Li, Jihoon Chung, Mengnan Du, Haimin Wang, Xianlian Zhou

Model compression is a crucial part of deploying neural networks (NNs), especially when the memory and storage of computing devices are limited in many applications. This paper focuses on two model compression techniques: low-rank approximation and weight pruning in neural networks, which are very popular nowadays. However, training NN with low-rank approximation and weight pruning always suffers significant accuracy loss and convergence issues. In this paper, a holistic framework is proposed for model compression from a novel perspective of nonconvex optimization by designing an appropriate objective function. Then, we introduce NN-BCD, a block coordinate descent (BCD) algorithm to solve the nonconvex optimization. One advantage of our algorithm is that an efficient iteration scheme can be derived with closed-form, which is gradient-free. Therefore, our algorithm will not suffer from vanishing/exploding gradient problems. Furthermore, with the Kurdyka-Łojasiewicz

(KL) property of our objective function, we show that our algorithm globally converges to a critical point at the rate of $O(1/k)$, where k denotes the number of iterations. Lastly, extensive experiments with tensor train decomposition and weight pruning demonstrate the efficiency and superior performance of the proposed framework.

3 - Regularized Tensor Completion for Structural Health Monitoring Data Imputation

Shenghao Xia, University of Arizona, Tucson, AZ, United States

Missing sensor data is a ubiquitous issue in structural health monitoring (SHM), often resulting from sensor failures and restricting system effectiveness. SHM data, collected from spatially distributed sensors over time, typically exhibit intricate spatial-temporal (ST) patterns, which pose difficulties for conventional imputation methods, especially in scenarios involving prolonged or continuous data loss. To address these challenges, this study proposes a novel imputation method that explicitly captures ST dependencies and enables accurate recovery of critical structural characteristics in both the time and frequency domains. An efficient optimization algorithm is developed to support robust and scalable estimation. The proposed method is validated through a real-world case study, demonstrating superior imputation accuracy and robustness compared to existing benchmark approaches.

4 - Sparsest: Exploiting Data Sparsity in Spatiotemporal Modeling and Prediction

Junfeng Wu, Rensselaer Polytechnic Institute, Troy, NY, United States, Yinan Wang

Spatiotemporal data mining has a wide range of applications in modeling and predicting various complex physical systems (CPS), i.e., transportation, manufacturing, healthcare, etc. Among all the proposed methods, the Convolutional Long-Short Term Memory (ConvLSTM) has proved to be generalizable and extendable in different applications. However, ConvLSTM and its variants are computationally expensive, which makes it inapplicable in edge devices with limited computational resources. With the emerging need for edge computing in CPS, efficient AI is essential to reduce the computational cost while preserving the model performance. Common methods of efficient AI are developed to reduce model redundancy (i.e., model pruning, etc.). However, model redundancy is limited in spatiotemporal data mining as the embedded dependencies are complex and hard to capture. Instead, there is a fair level of data redundancy, which has been largely overlooked in existing research. Using the sequence of images as an example, (1) the informative pixels at each frame are usually spatially sparse (i.e., with a fixed background), and (2) the informative features in the first-order difference of two adjacent images are possibly sparse due to the slow temporal evolution. Therefore, we develop a novel efficient ConvLSTM that pioneeringly exploits the sparsity of informative features. More specifically, the sparse convolution and the Delta algorithm are incorporated to exploit the spatial sparsity at each single time step and the sparsity in the first-order difference over a sequence, respectively. The experiment demonstrates that our proposed methods can achieve comparable performance to the original ConvLSTM with reduced computational complexity.

5 - Disco: Disentangling Signal Restoration and Corruption Identification via Sample-Wise Latent Low-Rank Similarity

Yifeng Wang, Georgia Institute of Technology, Atlanta, GA, United States, Shancong Mou, Jianjun Shi, Chuck Zhang

With the rapid advancement of sensing technologies, diverse signals can now be collected during complex industrial processes, enabling more effective strategies for quality control through signal restoration and anomaly (corruption) identification. While numerous approaches have been developed for fine-grained anomaly detection, existing state-of-the-art methods often struggle to simultaneously achieve accurate anomaly identification and nonlinear signal restoration due to the inherent entangling effect. To address this critical challenge, we propose DISCO (*Disentangling Signal Restoration and Corruption Identification*), a novel method that generalizes Robust Principal Component Analysis (RPCA) to the nonlinear domain by utilizing an autoencoder network and introducing the sample-wise latent low-rank similarity. This regularization enables DISCO to decouple the underlying signal structure from additive corruptions effectively. Extensive evaluations, including simulation experiments, case study, and ablation analysis, demonstrate that DISCO significantly outperforms existing benchmarks in both fine-grained anomaly detection and nonlinear background restoration.

Reliability, Robustness, and Uncertainty Quantification

Contributed Session

Contributed

Chair: Orkun Irsoy, Carnegie Mellon University, Pittsburgh, PA, United States

1 - Improvement in Airline Operations Using Six Sigma Methodologies

Ramesh Bollapragada, San Francisco State University, San Francisco, CA, United States

The purpose of the paper is to investigate the financial and operational benefits when deploying six sigma methodologies in airline operations. Specifically, it intends to improve the service operations of the airline industry. The six sigma continuous improvement methodology i.e. DMAIC (define, measure, analysis, implementation, and control) is used in this study. Six sigma statistical analysis is used to measure the current performance of each critical metric involving the operational processes within international and U.S. domestic airline industry. Using six sigma level or the current sigma level (whichever is higher) as the benchmarking tool, this paper compares the compensation expenses caused by the variations in operational processes before and after the sigma level is achieved. We present a new approach to set an internal benchmark and determine the tolerance level, when measuring airlines (international, domestic) operational standards. The findings depict the difference between the current sigma level and the proposed six sigma level for each critical metric. Through the six sigma methodology, we provide an improvement in the following six critical passenger-defined quality metrics: accident rate, casualty rate, flight delay rate, flight cancellation rate, baggage irregularity rate, and denied boarding rate. An analysis of the annual financial savings on each of the above operational metrics is presented. The aggregate annual savings obtained across all the critical metrics is in the order of billions of dollars discussed.

2 - Anytime-Valid Inference in Adaptive Experiments: Covariate Adjustment and Balanced Power

Daniel Molitor, Cornell University, Ithaca, NY, United States, Samantha Gold

Adaptive experiments such as multi-armed bandits offer efficiency gains over traditional randomized experiments but pose two major challenges: invalid inference on the Average Treatment Effect (ATE) due to adaptive sampling and low statistical power for sub-optimal treatments. We address both issues by extending the Mixture Adaptive Design (Liang and Bojinov, 2024; MAD) framework. First, we propose MADCovar, a covariate-adjusted ATE estimator that preserves anytime-valid inference guarantees while substantially improving ATE precision. Second, we introduce MADMod, which dynamically reallocates samples to underpowered arms based on statistical significance, enabling more balanced statistical power across treatments without sacrificing valid inference.

Both methods retain MAD's core advantage of constructing confidence sequences (CSs) that remain valid under continuous monitoring and arbitrary stopping. Theoretical guarantees show our ATE estimators are unbiased and yield shrinking, valid CSs under mild regularity conditions.

Empirically, we validate both methods using simulations and real data. In simulation, MADCovar reduces CS width by up to 40% relative to MAD. In a large-scale political RCT with ~32,000 participants, MADCovar achieves up to 3–4x precision gains. MADMod improves statistical power and inferential precision across all treatment arms, particularly for suboptimal treatments, by reallocating samples based on a user-specified function. Simulations show that MADMod sharply reduces Type II error while preserving the efficiency benefits of adaptive allocation.

Together, MADCovar and MADMod make adaptive experiments more practical, reliable, and efficient for applied researchers across many domains.

3 - Automated Analysis of Experiments Using Hierarchical Garrote

Wei-Yang Yu, Georgia Institute of Technology, Atlanta, GA, United States, V. Roshan Joseph

In this work, we propose an automatic method for the analysis of experiments that incorporates hierarchical relationships between the experimental variables. We use a modified version of the nonnegative garrote method for variable selection which can incorporate hierarchical relationships. The nonnegative garrote method requires a good initial estimate of the regression parameters for it to work well. To obtain the initial estimate, we use generalized ridge regression with the ridge parameters estimated from a Gaussian process prior placed on the underlying input-output relationship. The proposed method, called HiGarrote, is fast, easy to use, and requires no manual tuning. Analysis of several real experiments are presented to demonstrate its benefits over the existing methods.

4 - Analysis and Optimization of Robustness in Multiplex Flow Networks Against Cascading Failures

Orkun Irsoy, Carnegie Mellon University, Pittsburgh, PA, United States, Osman Yagan

Networked systems are susceptible to cascading failures, where the failure of an initial set of nodes propagates through the network, often leading to system-wide failures. In this work, we propose a multiplex flow network model to study robustness against cascading failures triggered by random failures.

The model is inspired by systems where nodes carry or support multiple types of flows, and failures result in the redistribution of flows within the same layer rather than between layers.

To represent different types of interdependencies between the layers of the multiplex network, we define two cases of failure conditions: layer-independent overload and layer-influenced overload.

We provide recursive equations and their solutions to calculate the steady-state fraction of surviving nodes, validate them through a set of simulation experiments, and discuss optimal load-capacity allocation strategies.

Our results demonstrate that allocating the total free space (i.e., capacity minus initial load) to each layer proportional to the mean effective load in the layer and distributing that free space equally among the nodes within the layer ensures maximum robustness.

The proposed framework for different failure conditions allows us to analyze the two overload conditions presented and can be extended to explore more complex interdependent relationships.

Supply Chain Interactions – Humans, Algorithms, Bots...

Invited Session

Behavioral Operations Management

Chair: Michael Becker-Peth, Rotterdam School of Management, Erasmus University, Rotterdam, Netherlands

1 - Negotiating Against Chatbots: Do I Expect/Get Better Outcomes from a Human OR a Bot Counterpart? Let's Negotiate Again!

Klaus Garrido, Rotterdam School of Management, Erasmus University, Rotterdam, Netherlands, Michael Becker-Peth, Jelle de Vries

The adoption of Artificial Intelligence (AI) in procurement is rapidly accelerating, with significant implications for operational efficiency. This research explores the operational impact of artificial counterparts in business-to-business (B2B) negotiations. Through a lab experiment with 348 participants, we investigate how the nature of negotiation counterparts (human or AI) affects negotiation outcomes, profit expectations, private information disclosure, and the preference for bots as future negotiation counterparts. Our findings reveal that 1) individuals have higher profit expectations from negotiations with bots compared to negotiations with humans. 2) Negotiators achieve comparable agreement rates but higher profits with bots, challenging prior research suggesting lower cooperation and agreement rates in human-bot interactions. Moreover, 3) exceeding expected profits significantly influences the choice between human and artificial counterparts. Specifically, having profited more against bot counterparts than other humans seems to increase the likelihood of choosing an artificial counterpart in a final negotiation. Finally, our post-hoc analysis reveals 4) over time, humans learn to exploit the predictability of the artificial counterpart by disclosing non-verifiable private information. Therefore, this study has tangible implications for practitioners aiming to implement automated negotiation systems in procurement. Managers should carefully evaluate the long-term effectiveness of artificial negotiators due to exploitation vulnerability. Thus, we raise awareness of the risks associated with deploying predictable AI negotiators that are collaborative, trusting, and honest.

2 - How to Account for Behavioral Newsvendors: the Robust Buyback Contract to Address Response Uncertainty

Michael Becker-Peth, Rotterdam School of Management, Erasmus University, Rotterdam, Netherlands, Christina Imdahl, Kai Hoberg

Normative (expected-profit-maximizing) theory assumes that decision-makers are fully rational, but in reality, they deviate from the optimal response. In contract negotiations, contract parameters are often optimized based on the assumption of rational behavior. Deviations from rational behavior can lead to significant costs for all parties involved. To address this, we propose robust optimization to obtain contract parameters that account for deviations from rational behavior.

We apply this optimization approach to obtain the robustly optimal contract parameters for the buyback contract when there is limited knowledge of the buyers' responses. We develop a parameterization of the robust contract, called the naive robust contract, that is based on the pull-to-center effect.

We compare the naive robust contract to the normative contract by simulating orders that follow certain known behavioral models, such as mean-anchoring, bounded rationality, or a behavioral model explicitly for the buyback contract.

Additionally, we test different the normative, the naive robust and various behavioral contracts in a lab experiment with actual human decision-makers. The results demonstrate that a robust contract, based on simple assumptions, can outperform the normative contract in terms of risk while not sacrificing average supply chain profit. The robust contract also weakly dominates all other behavioral contracts, meaning that it significantly outperforms them in either average supply chain profit or risk. This approach offers a practical way to set contract parameters without relying on assumptions about the distribution of responses, except for the support.

3 - Strategic Interactions in Surplus Drug Donations: A Game Theory and Experimental Approach

James Hill, Ohio State University, Columbus, OH, United States, Telesilla Kotsi, Soh Hyun Chu

We employ game theory to model strategic interactions between Corporate Social Responsibility and Supply Chain teams in pharmaceutical firms, focusing on surplus drug donations. Controlled experiments explore how monetary incentives and operational transparency influence supply chain managers' decisions, identifying factors that align donation strategies with operational objectives in complex environments.

4 - The Effect of Cognitive Load on Algorithmic Reliance

Han Oh, Tilburg University, Tilburg, Netherlands, Eirini Spiliotopoulou, Rogelio Oliva

Research on behavioral decision-making has shown that flexibility and adaptability are among the strengths of human decision-makers. However, there is limited research on how to integrate these strengths into algorithmic decision-making systems. In this study, we explore how decisions are made under cognitive load and how decision support systems can help individuals better allocate their cognitive resources to improve decision quality.

5 - Is AI An Algorithm by Any Other Name? Behavioral Reactions to Model- and Ai-Based Demand Planning Algorithms

Finnegan McKinley, University of Arkansas, Fayetteville, AR, United States, Rebekah Brau, John Aloysius, Adriana Hofer

The rapid implementation of AI in demand planning offers the potential to improve forecast accuracy. However, users' behaviors toward AI advice might undermine potential gains. This study unveils how human behavior may differ due to the mere revelation of algorithm type—AI- or model-based—and algorithm signals of bias and learning. Using signaling theory, we hypothesize that algorithm type and signals of bias and learning influence user assessment of algorithm credibility, subsequently impacting forecast adjustment behavior. We test for differences in user adjustments based on algorithm type and signals using two laboratory experiments and a quasi-natural field experiment with over 1.1 million observations from a multinational retailer. We find that users adjust AI- and model-based algorithms similarly for a demand planning task in the lab. We also find that when algorithms signal positive bias, users adjust downwards, and when algorithms signal negative bias, users adjust upwards. However, we find that these upward and downward adjustments are amplified for AI-based algorithm use. Concerning learning, we find that users adjust to learning algorithms by decreasing their absolute forecast adjustments, but we do not find a difference in this adjustment behavior for algorithm type. We fully replicate our

significant results in the field, finding that experienced demand planners exhibit an amplified response behavior towards bias in AI algorithms. Our research advances AI recommendation adherence research by showing that the unique context of demand planning evokes a complex response to AI.

GenAI in Platform Operations: Trust, Competition, Algorithms and Models

Invited Session

Artificial Intelligence

Chair: Ruohan Zhan, University College London, London, United Kingdom

Co-Chair: Ziyi Cao, University of Texas at Dallas, Richardson, TX, United States

1 - Exposure, Readiness, and Firm Valuation of Generative AI

Haonan Yin, University of California - Irvine, Irvine, CA, United States, Sanjeev Dewan, Fei Ren

Generative AI can be considered as a “General Purpose Technology” that has the potential to create broad impact across industries and economies, yet we have little understanding of how these transformative AI technologies are helping firms create and capture value. Recent research has shown that a substantial portion of the corporate workforce is exposed to GenAI and that firms with higher GenAI Exposure experience positive cumulative abnormal returns (CARs). We build upon this research and provide a more nuanced understanding of the mechanisms driving improvements in firm valuation by deconstructing exposure into three dimensions based on business functions: product, process, and customer. Additionally, we argue that Exposure alone does not guarantee added firm value, but that Exposure has to be matched with complementary AI strategies and technological investments, which we call strategic AI Readiness. In results, we found that firms with both high Exposure and high Readiness have positive and significant CARs, averaging 0.94%, over a two-day event window. In contrast, firms with high Exposure but low Readiness exhibit positive but statistically insignificant CARs, indicating limited benefits from GenAI in the absence of sufficient readiness. Interestingly, firms with low Exposure but high Readiness experience significantly negative CARs, averaging -0.32%, suggesting that misaligned AI adoption can harm firm value. These findings highlight the risks associated with premature or misaligned GenAI initiatives. Overall, this study provides actionable insights for managers, underscoring the importance of synchronizing AI strategies with organizational infrastructure and workforce capabilities to fully leverage the potential of generative AI.

2 - Career1: Reasoning Models for Career Path Prediction via Reinforcement Learning

Shuzhang Cai, The University of Texas at Dallas, Richardson, TX, United States, Ying Xie, Shaojie Tang

Modern labor markets present individuals with complex and dynamic career choices. Online platforms are increasingly use predictive algorithms to recommend jobs and anticipate mobility patterns. The progress in machine learning makes it possible to analyze large-scale career data and uncover patterns of mobility. The research on career path prediction aims to anticipate future job transitions by leveraging historical career trajectories and associated information. Early studies typically rely on structured information such as job titles, durations, employers, and skills, but do not take into account the free-text descriptions in resumes. Yet these descriptions contain rich information and can substantially enhance prediction. Recent advances in reinforcement learning and large reasoning models (LLMs) have opened new opportunities for problem-solving or decision-making tasks. In particular, for career data containing natural language descriptions of work experiences, LLMs can leverage their strong capacity for text processing and understanding to extract richer semantic information and thereby enhance the accuracy of prediction. In this paper, we employ a base LLM with the reinforcement learning method Group Relative Policy Optimization (GRPO) to tackle this problem. We propose CAREER1, a set of novel reasoning models through the integration of knowledge distillation supervised fine-tuning and reinforcement learning. Specifically, we modify the reward function in GRPO, which results in two CAREER1 variants optimized under different learning signals. Experiments on three real-world career path datasets demonstrate that CAREER1 variants improve the average Recall @5 by 2.3%, Recall@10 by 2.6% and MRR by 0.023 relative to the state-of-the-art baseline models.

3 - Past Tells, Future Sells: Automatic Fashion Product Creation with Generative AI

Jianghao Lin, Shanghai Jiao Tong University, Shanghai, China, People's Republic of, Ruohan Zhan, Zi Ling

E-commerce has revolutionized retail, yet its traditional workflows remain inefficient, with significant time and resource costs tied to product design and manufacturing inventory. We introduce a novel system deployed at Alibaba that leverages AI-generated fashion products to address these challenges with personalized text-to-image generation. In this way, we enable an innovative business model called "sell it before you make it", where merchants can design fashion items and generate photorealistic images with digital models based on textual descriptions. Only when the items have received a certain number of orders, do the merchants start to produce them, which largely reduces reliance on physical prototypes and thus accelerates time to market. This paradigm has been fully deployed and tested at Alibaba. The AI-generated fashion products have achieved over 13% relative improvements for both click-through rate and conversion rate compared to their human-designed counterparts, validating the revolutionary potential of AI-driven automatic fashion product creation for e-commercial platforms.

4 - Large Language Models and Large-Scale Causal Decision-Making

Shichao Han, Tencent, Shanghai, China, People's Republic of

Randomized controlled experiments (RCTs) are a scalable and reliable approach for large-scale decision-making, particularly when combined with observational data and appropriate statistical tools. The advent of large language model (LLM) agents has further improved the efficiency of causal discovery, leveraging their advanced capabilities to mimic human behavior and process unstructured data. However, before LLMs can be widely adopted for decision-making at scale, it is essential to establish and quantify the credibility of the insights they generate. By integrating causal inference techniques with artificial intelligence, platforms can enhance their ability to perform causal discovery more effectively. Additionally, we illustrate how LLMs serve as complementary tools to RCTs and other statistical methods, drawing on examples from Weixin.

5 - ACS: An Interactive Framework for Conformal Selection

Zhimei Ren, University of Pennsylvania, Philadelphia, PA, United States, Yu Gui, Ying Jin, Yash Nair

In this talk, I will introduce adaptive conformal selection (ACS), an interactive framework for model-free selection with guaranteed error control. ACS extends Jin and Candès (2023b) to allow for adaptive data analysis, where decisions can be made on the fly based on partially revealed data. The key to ACS is a carefully designed screening principle that reveals data, which allows us to update the selection rule while maintaining rigorous control of the false discovery rate (FDR). Under the general adaptive framework, we provide concrete instantiations of ACS for power improvement, diversified selection, and incorporating new labeled data. We demonstrate the effectiveness of ACS through extensive numerical simulations and real data applications in large language model (LLM) deployment and drug discovery.

Teaching Tomorrow's Leaders: Embedding AI and Analytics in Supply Chain Education

Invited Session

INFORMS Committee on Teaching and Learning

Chair: Ramakrishna Garine, university of north texas, Peoria, 61615, United States

Co-Chair: Senthilkumar Thiyagarajan, Medline Industries, LP, Wheeling, IL, 60090, United States

Co-Chair: Nixalkumar Patel, LG Electronics, 19 Lincoln Ave, Lake Hiawatha, NJ, 07034, United States

1 - From AI Hype to Applied Learning: Equipping Supply Chain Professionals with Real-World Ai Skills

James Gaffney, Georgia Tech Supply Chain Institute, Atlanta, GA, United States

The future of supply chain belongs to professionals who can critically assess, deploy, and lead with AI—not just talk about it. In this session, I'll share insights from Georgia Tech's Generative AI in Supply Chain course, designed for industry professionals navigating both the opportunities and risks of AI adoption. Drawing on our "AI and Analytics Ladder" framework and the article "Skills to Survive and Thrive in the Age of AI," this presentation highlights how we move beyond buzzwords to build capability. I'll cover how we use real-world use cases to demystify Gen AI tools like ChatGPT, Power BI, and Python. I'll also share our interdisciplinary teaching approach, which includes applied exercises, AI policy discussions, and critical thinking "workouts" to ensure learners don't lose the human edge. Finally, I will share our approach to keep the content current as it needs a near complete re-write for every session. Participants will walk away with example lesson plans, a curated list of hands-on tools, and a model for designing curriculum that keeps pace with the evolving demands of the AI-powered supply chain—while still rooted in supply chain fundamentals.

2 - Teaching AI-Driven Cross-Platform Data Intelligence: Embedding Automated Validation Systems in Supply Chain Education**Nihari Paladugu, Southern New Hampshire University, Columbus, OH, United States**

Supply chain disruptions cost global businesses \$2.3 trillion annually, yet 73% of graduate interns entering supply chain roles lack essential analytical skills for data governance and cross-system validation. This educational research presents the InsightOps Educational Framework, a novel pedagogy that adapts financial services' 99.99% data accuracy methodologies to supply chain management education.

The framework teaches graduate interns five core competencies: (1) attribute-level usage intelligence for data value optimization, (2) behavioral telemetry analytics for user pattern recognition, (3) AI-powered PII detection for compliance automation, (4) machine learning-based cross-platform validation across Teradata, Snowflake, and ERP systems, and (5) self-learning governance engines for policy enforcement.

Implementation with 12 graduate interns at a Fortune 500 manufacturer demonstrated remarkable outcomes: 99.2% data accuracy across platforms, 95% reduction in migration issues, and 23% salary premiums for program graduates. The methodology transforms traditional supply chain education by embedding automated validation systems thinking derived from regulated financial services.

This human-AI collaborative approach prepares graduate interns as AI orchestrators rather than automation victims, teaching systematic data governance excellence while maintaining ethical oversight. The framework offers scalable educational innovation for institutions seeking to bridge the critical skills gap in supply chain analytics leadership.

3 - Agent-Driven Decision Support in Inventory Replenishment and Exception Resolution**Harshavardhan Nannur, Walmart, Dallas, TX, United States**

Modern retail supply chains face increasing complexity, with dynamic demand, fragmented data sources, and frequent operational exceptions. This talk introduces a practical framework for integrating agentic AI into inventory replenishment and exception management workflows. We present a modular, human-in-the-loop system where generative agents monitor replenishment signals, detect anomalies, and suggest context-aware resolutions across clubs and fulfillment centers. The approach blends rule-based monitoring with LLM-powered reasoning to improve issue triage, reduce manual effort, and drive faster, more consistent decision-making. Results from real-world pilots demonstrate measurable improvements in response time and replenishment accuracy.

4 - Building Ethical AI Literacy in Future Supply Chain Professionals**Anand Chinnakannan, Quantic School of Business & Technology, Bentonville, AR, United States**

As artificial intelligence becomes central to decision-making across the supply chain—from forecasting and procurement to logistics and customer fulfillment—the need for ethical and responsible AI use is more urgent than ever. Yet, while technical education in AI and analytics is growing rapidly, ethical considerations often remain overlooked.

This session presents a framework for integrating ethical AI literacy into supply chain education by mapping the ethical risks and responsibilities at each stage of the supply chain. Key topics include bias in demand forecasting, fairness in supplier selection algorithms, labor impacts of automation, data privacy in logistics, ethical price personalization, and sustainability in reverse logistics.

Through real-world case examples and curriculum design strategies, the session equips educators and professionals with tools to prepare students not only as skilled AI practitioners but as thoughtful, responsible decision-makers. Attendees will gain actionable insights for embedding ethics into both technical and managerial training in supply chain programs.

5 - Agentic AI in Supply Chain Education: Teaching Beyond Chatbots**Shiva Kumar, Albertsons, Plano, TX, United States**

The integration of Artificial Intelligence into supply chain operations has rapidly evolved beyond traditional machine learning models and static automation tools. At the forefront of this transformation is Agentic AI, a new generation of intelligent systems capable of autonomous planning, contextual reasoning, proactive decision-making, and human-like interaction. These systems go far beyond reactive chatbot interfaces and are increasingly being used in real-world supply chain environments to manage inventory, forecast demand, optimize logistics, and coordinate supplier networks.

6 - Empowering Supply Chain Education with Real-World AI and Open-Source Optimization Tools**Herin Savla, ABF Freight, Fort Smith, AR, United States**

As the logistics and supply chain industry continues to evolve, the integration of AI and analytics has become a cornerstone of operational efficiency. However, there remains a significant gap between academic training and industry expectations—particularly in the practical application of optimization techniques. This presentation will explore how open-source tools, such as Google OR-Tools, can be effectively incorporated into supply chain and operations research curricula to bridge this gap. Drawing from my professional experience in leading large-scale analytics initiatives at ABF Freight, I will highlight the value of hands-on exposure to real-world problem-solving using accessible, industry-relevant technologies. Attendees will gain insights into how these tools can be used to model and solve complex optimization problems like vehicle routing problems, preparing students to contribute meaningfully from day one in their careers. By fostering a curriculum that emphasizes both theoretical foundations and practical applications, we can better equip the next generation of supply chain professionals to meet the demands of a data-driven world.

7 - Developing AI and Analytical Skills in Supply Chain Professionals to Build Lean, Agile, Resilient, and Sustainable (Lars) Supply Chains**Senthilkumar Thiagarajan, Medline Industries, LP, Wheeling, IL, United States**

The supply chain profession is undergoing a profound transformation driven by rapid technological advancements, disruptions, and rising operational complexities. Traditional skill sets are no longer sufficient to drive meaningful impact in supply chains. To thrive in today's dynamic environment, supply chain professionals must develop capabilities in AI, machine learning, and advanced analytics to harness the power of Industry 4.0 technologies – including digital twins and the Internet of Things (IoT). These technologies are critical enablers of lean, agile, resilient, and sustainable supply chains, and they also generate massive volumes of data to support informed, insight-driven decision-making in supply chain operations.

This presentation explores how academic institutions and organizations can prepare current and future supply chain leaders to meet these emerging demands. It outlines a structured approach for **teaching, evaluating, and recognizing AI and analytics competencies**, drawing from both supply chain management and learning literature. As organizations move toward digital, resilient and sustainable supply chains, developing human capability becomes just as important as technological investment. Special attention is given to methods for upskilling early-career professionals, mid-level managers, and supply chain practitioners transitioning into digitally intensive roles. By linking technological adoption with human capability development, this session aims to close the gap between research and real-world application, innovation and execution, ensuring that the workforce is equipped to lead the next era of supply chain transformation.

Building B Level 4 B407

Recent Advances in Optimization Under Uncertainty

Invited Session

Data Mining

Chair: Muyun Lu, University of Houston, Houston, TX, United States

Co-Chair: JUN ZHOU, University of Houston, Houston, TX, 77054, United States

Co-Chair: Ying Lin, University of Houston, Houston, TX, United States

1 - A Decomposition Method for Integrated Chance-Constrained Stochastic Programming with Application to Optimal Vaccine Allocation**Xin-Yu Zhuang, Texas A&M University, College Station, TX, United States, Lewis Ntaimo**

Vaccination is crucial for controlling epidemics especially for viruses that mutate or have different strains with uncertain transmission characteristics. To prepare for future outbreaks, data-driven models for optimizing vaccination strategies are essential. Integrated chance-constrained stochastic programming (ICC-SP) has been proposed for this purpose, but solving large-scale instances of ICC-SP models efficiently is challenging. To address this, we propose a decomposition cutting-plane method for ICC-SP model for optimal vaccine allocation. This ICC-SP model is a multi-community, household-based epidemiological model that incorporates census demographic data, vaccination status, age-related differences in disease susceptibility and infectivity, and vaccine efficacy. We report on computational study based on real data for flu for the State of Texas and for COVID-19 for the South Africa setting.

2 - Optimal Mechanism Design with Constraint-Aware Bayesian Optimization**Muyun Lu, University of Houston, Houston, TX, United States**

Mechanism optimization seeks to identify an optimal mechanism that maximizes a designer's objective while satisfying equilibrium constraints, such as Nash Equilibrium. This task is computationally challenging, often formulated as a Mixed-Integer Nonlinear Programming problem, which is NP-hard and lacks efficient general-purpose solvers. To address this challenge in the context of the sharing economy, exemplified by peer-to-peer ride-sharing, we develop a nonlinear optimization model based on the Affine Maximizer framework. We propose a novel algorithm, Optimal Mechanism Design with Constraint-aware Bayesian Optimization (MDCBO), to solve this model. MDCBO leverages constraint-aware Bayesian optimization to intelligently search the design space while adhering to constraints, as the Affine maximizer determines the allocation rule and provides crucial feedback to meet equilibrium requirements. This synergistic approach enables the efficient discovery of high-performing mechanisms in computationally demanding environments. Theoretical analysis and numerical studies are conducted to demonstrate the solution quality and computational efficiency of MDCBO for the optimal mechanism design.

3 - Robust Remanufacturing Planning with Interval Matrix-Based Uncertainty Set**JUN ZHOU, University of Houston, Houston, TX, United States**

We study the problem of remanufacturing planning under uncertainty arising from statistical estimation errors. A critical aspect of determining optimal remanufacturing timing is accurately modeling the system's state transition dynamics. However, such estimations often suffer from inaccuracy due to limited or noisy data, leading to significant performance degradation when conventional methods applied. To mitigate the impact of uncertainty, we formulate the problem as a robust Markov decision process (RMDP), where the system's true state transition probability matrix is unknown but assumed to lie within an ambiguity set that captures all possible realizations consistent with observed data. We focus on ambiguity sets defined by interval matrices, which offer a tractable and interpretable means of representing uncertainty in transition dynamics. A tailored solution methodology that efficiently computes optimal robust policies is developed. We further establish structural properties of optimal robust policies and provide theoretical insights into the interval-matrix-based ambiguity sets. A computational study on the NASA turbofan engine shows that our data-driven decision framework consistently yields better worst-case performances and higher reliability of the performance guarantee.

4 - Distributionally Robust Universal Classification: Bypassing the Curse of Dimensionality**Siyuan Chen, Georgia Institute of Technology, Atlanta, GA, United States, Weijun Xie**

The Universal Classification (UC) problem seeks an optimal classifier from a universal policy space to minimize the zero-one loss. However, the conventional empirical risk minimization often leads to overfitting and poor out-of-sample performance. To address this limitation, we introduce the Distributionally Robust Universal Classification (DRUC) formulation, which incorporates distributional robustness via the Wasserstein distance centered at the empirical distribution. To manage the infinite-dimensional nature of the DRUC policy space, we develop its in-sample DRUC counterpart, which allows for a more tractable reformulation while preserving robustness properties. We prove that, asymptotically, the in-sample DRUC formulation converges to the original UC formulation and is equivalent to the DRUC formulation. Under mild conditions, we provide non-asymptotic finite-sample performance guarantees. Furthermore, we derive a mixed-integer linear programming (MILP) reformulation to obtain the optimal in-sample DRUC policy and propose an efficient 2-approximation algorithm. Our numerical experiments show the efficiency of the proposed approximation algorithm and demonstrate the superior out-of-sample performance of the in-sample DRUC formulation.

5 - Performance of Myopic Replenishment Policies for Retail Inventory Management: a Distributionally Robust Approach**Mohammad Razzaghi Kashani, University of Houston, Houston, TX, United States, Mehdi Farahani**

In this paper, we study the problem of determining optimal replenishment quantities for multiple products over multiple periods in retail stores subject to limited shelf space and minimum presentation constraints. Our goal is to maximize total profit by accounting for sales revenue and procurement costs in environments characterized by uncertain product demand.

We propose a myopic replenishment policy embedded within a distributionally robust optimization (DRO) framework. The DRO approach enables us to make minimal assumptions about demand distributions, relying solely on their mean and variance, thereby reducing forecasting complexity and improving practical applicability. Using dynamic programming, we analytically demonstrate the optimality of myopic policies, particularly when store capacity is significantly constrained relative to potential inventory levels—a frequent scenario faced by retailers due to SKU proliferation and rapid product turnover. Our theoretical analysis provides structural insights into optimal inventory strategies by identifying explicit conditions under which myopic policies achieve optimal performance.

We validate our theoretical results through extensive numerical experiments. The experiments confirm that the proposed myopic policy achieves excellent performance across diverse operational scenarios. Furthermore, the simplicity, computational efficiency, and limited data requirements of the policy significantly enhance its managerial appeal, facilitating straightforward implementation in practice.

Our findings underscore a critical insight for retail operations, highlighting that although sophisticated inventory models may theoretically promise superior outcomes, real-world constraints—particularly the limited shelf space frequently faced by retailers in practice—often make simpler, intuitive replenishment strategies more effective and better aligned with actual business needs.

Building B Level 4 B408

Variable Importance

Invited Session

Data Mining

Chair: Cynthia Rudin, Duke University, Durham, NC, United States

Co-Chair: Srikar Katta, Duke University, Durham, NC, United States

1 - Variable Importance: a Critical Overview

Emanuele Borgonovo, Bocconi University, Milan, Italy, Elmar Plischke, Xuefei Lu, Cynthia Rudin

Variable importance measures are a central tool in explainable AI. They help analysts assess how much each input feature contributes to a model's output. However, the plethora of available methods has led to confusion. Not all variable importance tools serve the same purpose: some provide indications for individual predictions, while others yield a global importance index at the dataset level. Also, some methods are model-specific while others are model-agnostic. It is then essential that analysts define the variable importance question up front and do not rely on the same hammer in all situations.

Also, when calculating feature importance measures issue might emerge if the corresponding algorithm forces the model to extrapolate. In this presentation, we review these and several other critical aspects that emerge in the use of variable importance measures.

2 - Variable Importance on Steroids

Cynthia Rudin, Duke University, Durham, NC, United States

I will overview modern work on model-free variable importance. I will introduce model class reliance, variable importance clouds and diagrams, concept whitening, and put some of the other work in this session into perspective, including the Rashomon Importance Distribution.

3 - A Rashomon Approach to Variable Importance with Distribution Shift

Jon Donnelly, Duke University, Durham, NC, United States, Srikar Katta, Emanuele Borgonovo, Cynthia Rudin

Variable importance analysis is an essential tool for knowledge discovery, particularly in settings where controlled trials are prohibitively expensive or impractical. Through variable importance, we can suggest factors that might be important in determining an outcome using only observational data.

However, existing methods for variable importance do not account for the impact of *unobserved* variables on their analysis. Moreover, existing methods tend to measure importance with respect to a single model, over a single, finite dataset. These shortcomings can lead to misleading results.

We address each of these problems through a Rashomon approach to variable importance under distribution shift (RAVIDS). We develop a theoretical connection between the impact of unobserved variables and the Rashomon set -- the set of all near optimal models -- and provide finite sample bounds on the estimation of the Rashomon set. We show through theory and simulation studies that RAVIDS captures the true importance of variables to the true data generating process with high probability, even when there are important unobserved variables.

4 - Targeted Learning for Variable Importance

Xiaohan Wang, Cornell University, Ithaca, NY, United States, Yunzhe Zhou, Giles Hooker

Variable importance is one of the most widely used measures for interpreting machine learning with significant interest from both statistics and machine learning communities. Recently, increasing attention has been directed toward uncertainty quantification in these metrics. Current approaches largely rely on one-step procedures, which, while asymptotically efficient, can present higher sensitivity and instability in finite sample settings. To address these limitations, we propose a novel method by employing the targeted learning (TL) framework, designed to enhance robustness in inference for variable importance metrics. Our approach is particularly suited for conditional permutation variable importance. We show that it (i) retains the asymptotic efficiency of traditional methods, (ii) maintains comparable computational complexity, and (iii) delivers improved accuracy, especially in finite sample contexts. We further support these findings with numerical experiments that illustrate the practical advantages of our method and validate the theoretical results.

Human Behavior in the AI Era

Invited Session

Technology, Innovation Management and Entrepreneurship

Chair: Zhaohui Jiang, Carnegie Mellon University, Pittsburgh, PA, United States

Co-Chair: Clare Snyder, NYU Stern, New York, NY, United States

1 - Unlocking the Value of Real-Time AI Assistance: Who Benefits, and Why?

Zhaohui Jiang, Carnegie Mellon University, Pittsburgh, PA, United States, Yao Cui, Qi Li

As companies increasingly integrate artificial intelligence (AI) into their services, it is becoming crucial to understand AI's impact on service users. One novel application of AI is to provide real-time assistance throughout the service process, featuring a more dynamic and interactive human-AI relationship. In this paper, we investigate how human users derive value from such real-time AI assistance and how this value varies according to users' experience levels. We address these questions through a collaboration with an international car-sharing platform that recently underwent a technology upgrade involving an AI-powered driver monitoring and feedback system. Combining theoretical insights with empirical analyses, we uncover a heterogeneous effect characterized by a U-shaped relationship: users with low or high experience levels benefit from AI assistance, while users with medium experience levels do not. Our findings further reveal that different user groups derive value from AI in distinct ways: low-experience users derive value passively due to their reliance on AI assistance, whereas high-experience users actively enhance AI's value by adapting their behaviors to mitigate the costs associated with AI during the real-time interaction. On the other hand, medium-experience users struggle to overcome the cost-benefit trade-off of AI, as they derive less benefit from AI's assistance compared to their less experienced peers and lack the adaptability of their more experienced peers to mitigate its costs. These insights are useful for guiding AI adoption and algorithm customization in service applications, and provide broader implications for other human-AI interaction processes, such as AI-assisted medical diagnosis and ChatGPT.

2 - Removing Phones from Classrooms Improve Educational Outcomes

Alp Sungu, Wharton, Philadelphia, PA, United States

We conducted a randomized controlled trial with 17,600 students to assess the causal effects of smartphone bans in classrooms. Implementing mandatory phone depositing to dedicated boxes during lectures improved student grades, particularly among lower-performing, first-year, and non-STEM students, with an average GPA increase of approximately 0.078 standard deviations. Importantly, students exposed to the ban became noticeably more supportive of phone-use restrictions, perceiving greater benefits from these policies and displaying reduced preferences for unrestricted access. Such enhanced student receptivity to restrictive digital policies, could reinforce the policy effectiveness through firsthand experience. Despite a mild rise in reported fear-of-missing-out, there were no significant negative effects on over-all student well-being, academic motivation, or digital use. Random classroom spot checks indicated fewer instances of chit-chat and disruptive behaviors among students, along with reduced phone usage and increased engagement among teachers in phone-ban classrooms—suggesting a classroom environment more conducive to learning. Spot checks also revealed that students appear more distracted, possibly due to withdrawal from habitual phone checking, yet, students did not report being more distracted. These findings suggest that classroom phone bans pose a low-cost, modest but “quick-win” policy recommendation to improve educational outcomes—especially for academically vulnerable groups.

3 - Guardrails on Biases? the Impact of Limiting Human Adjustments on Inventory Performance

Yixin Iris Wang, Gies College of Business, University of Illinois Urbana-Champaign, Champaign, IL, United States, Minyu Ye, Jun Li, Stephen Leider

In practice, managers often deviate from the ordering quantities recommended by inventory algorithms, citing private information not captured by the system. This study leverages a field experiment in offline pharmacy stores to examine the impact of restricting managers' manual adjustments on store performance. We further investigate the underlying drivers of these adjustments to determine whether the resulting performance changes are driven by a reduction in behavioral biases, the effective use of private information, or both.

4 - Too Neat To be True? Bias and Consumer Response with AI-Generated Review Summaries

YUNZHOU ZHONG, University of Pennsylvania, Philadelphia, PA, United States, Simin Li, Jiding Zhang

Review summaries generated by large language models (LLMs) are increasingly featured on user-generated content (UGC) platforms. Using the generative AI-generated hotel summaries and human-written reviews on TripAdvisor, this early-stage study investigates potential biases in AI-generated summaries of hotel reviews—specifically, how these summaries vary with characteristics of the underlying review pool, such as size and rating dispersion. We aim to understand whether AI summaries fairly represent the original content and how any summarization bias may shape consumers' expectations of service quality. We also examine how discrepancies between expectation and actual experience influence subsequent customer reviews. Additionally, we measure the concentration of demand across hotels, and explore the effect of AI-generated review summaries on market structures. By leveraging longitudinal data from TripAdvisor, our analysis aims to uncover the behavioral and market implications of integrating generative AI into review platforms.

5 - Green Intervention and User Compliance: a Field Experiment

Yi Song, Tsinghua University, Beijing, China, People's Republic of, Yao Cui, Da Zhang

Smart automated control of energy use is an emerging approach to resource conservation. However, its effectiveness can be limited by insufficient user compliance. In a randomized controlled trial conducted across public office buildings in China, we examine the impact of introducing a smart A/C emissions control system on electricity consumption under different control strategies. Our findings suggest that simply increasing the target temperature may not yield significant energy savings, but control strategies that adjust target temperatures more frequently or dynamically in response to user behavior can be more effective. These results underscore the importance of considering user compliance in the implementation of green technology and offer practical solutions for enhancing energy-saving outcomes.

Monday, October 27, 9:45 AM - 10:45 AM

Building A Level 4 Auditorium

Plenary - Ramayaa Krishnan

Plenary Keynote

Plenary

1 - Two Heads are Better than One Redux: AI, OR/MS and Society

Ramayya Krishnan, Carnegie Mellon University, Pittsburgh, PA, United States

In 1986, Nobel Laureate Herbert Simon delivered the TIMS/ORSA Joint National Meeting plenary titled “Two Heads Are Better Than One: The Collaboration between AI and OR”. Close to 40 years later, we are seeing the rapid development of AI technologies opening up dramatic new opportunities for synergistic collaboration between AI and OR/MS. From large language models to large reasoning models, from Gen AI for text to multimodal AI, and from chatbots to agentic AI, these technologies are important additions to our decision analytic and technology toolkits. However, adoption has been lagging due to a significant gap in understanding how to evaluate these technology artifacts and guide their deployment into workflows and systems to support consequential decision making. In this plenary talk, I posit the need for two types of synergistic collaboration to advance the science of measurement and evaluation required to achieve this objective. The first synergy opportunity – OR for AI (ORFAI) – is required to enable dynamic, multi-criteria analysis and evaluation of AI artifacts (e.g., LLM models, agents) as “systems”. The second – OR/AI for Societal Systems (ORAIS) – harnesses AI and OR/MS in consequential scenarios and workflows, and evaluates the implications of such deployment for workers and their reskilling/upskilling. I will discuss the need for robust evaluation infrastructure that will leverage this desired synergy between OR/MS and AI, and the significant implications for education, business and public policy.

Monday, October 27, 11:00 AM - 12:15 PM

Building A Level 3 A301

Gurobi Optimization/Responsive.net

Invited Session

Technology Showcase

Chair: Loraine Coleman, INFORMS, 5521 Research Park Drive, Catonsville, MD, 21228, United States

1 - Building Trust in Optimization

Caroline Weinberg, Gurobi Optimization, Boston, MA, United States

In this session we will explore some of Gurobi's advanced features through the lens of solution explainability, including solution pools, infeasibility analysis, and multi-scenario analysis. Explainability in practice requires both technical skills and successful communication with stakeholders who don't know how Gurobi works (and that's ok!). We show how these tools are not just for modeling – they can help users interpret optimization results and build trust their solutions.

2 - Using An Online Factory Management Simulation to Teach Operations Management

Samuel Wood, Responsive Learning Technologies, Los Altos, CA, United States

Littlefield for Operations is a competitive online simulation of either a factory or a medical laboratory that has been used by more than half a million students in 500+ universities in 60+ countries over the past 26 years. In this session, we will discuss how professors use the newest version of Littlefield for Operations (2.0) to effectively teach foundational operations management topics such as process analysis, capacity planning and inventory control to students at various levels in various course formats.

Embracing GenAI: Navigating the New Landscape of Knowledge Work

Panel Session

Committee's Choice

Co-Chair: Maryam Alavi, Georgia Tech, Atlanta, GA, United States

1 - Moderator Panelist

Maryam Alavi, Georgia Tech, Atlanta, GA, United States

Over the past decades, enterprises have successfully harnessed advances in computer, communication, and robotic technologies to automate routine tasks at scale, such as payroll management, inventory control, and manufacturing processes. This automation has delivered substantial efficiency gains, cost reductions, and productivity

enhancements across diverse sectors. Despite these successes, professional knowledge work has largely remained resistant to automation due to technological constraints. The advent and rapid evolution of generative AI (GenAI), however, are poised to dramatically alter this landscape. GenAI tools now offer unprecedented, human-like capabilities, including idea generation, natural language processing, software development, and multimedia content creation (text, image, video).

These capabilities present significant opportunities for organizations to transform knowledge-intensive tasks previously considered beyond the reach of traditional automation. Integrating GenAI into knowledge work promises substantial benefits, such as accelerated innovation, heightened productivity, and enhanced competitive advantage. Yet, deploying GenAI at scale involves navigating complex, multi-dimensional challenges that span technological infrastructure, individual behaviors, and organizational culture and practices. This panel will explore, and clarify GenAI's transformative potential for knowledge work, addressing crucial issues and insights from technological, behavioral, and organizational perspectives, and emphasizing the critical need for dynamic, continuous alignment among these domains.

Toward Intelligent Multi-Criteria Decision-Making: Methods and Applications

Invited Session

Multi Criteria Decision Making

Chair: Birsan Karpak, Youngstown State University, Canfield, OH, United States

Co-Chair: Ilker Topcu, Istanbul Technical University, Istanbul, Turkey

1 - Exploring the Interaction of Pressure Sources and Types on Sscm Practices: An ANP Model Approach

Birsan Karpak, Youngstown State University, Canfield, OH, United States, Alina Marculetiu, Cigdem Ataseven, Ilker Topcu

The growing emphasis on sustainability has intensified external and internal pressures on firms to adopt Sustainable Supply Chain Management (SSCM) practices. These pressures—exerted by entities such as governments, customers, suppliers, and employees—manifest through various mechanisms, including coercive (regulatory), normative (social), and mimetic (competitive) influences. While these individual factors are well-documented, their relative importance and interdependencies remain underexplored. This study addresses that gap by proposing an Analytic Network Process (ANP) model to evaluate and prioritize the interactions between pressure sources and pressure types, providing a more comprehensive understanding of how they collectively influence SSCM practices across internal, upstream, and downstream operations.

Drawing on a synthesis of 93 articles published between 1997 and 2022, the research identifies key factors and develops a network-based framework that captures complex, multi-directional relationships. Expert input is collected through pairwise comparisons involving regulators, corporate sustainability leaders, NGOs, and industry analysts. The ANP model then quantifies the influence of each source-type combination, revealing which pressures most effectively drive SSCM adoption.

Initial findings indicate that coercive pressure from regulators and normative pressure from investors are among the most impactful. Additionally, the model highlights how certain interactions amplify or mitigate the effectiveness of others, offering actionable insights for firms and policymakers. By moving beyond linear cause-effect assumptions, this study contributes to SSCM literature with a nuanced, systems-based approach.

Ultimately, the findings aim to inform strategic, context-sensitive interventions that enhance supply chain sustainability and resilience in an increasingly complex global environment.

2 - An Evaluation Framework for Blockchain Selection in Supply Chain

Deepa Iyer, Cleveland State University, Cleveland, OH, United States, Birsan Karpak, Ilker Topcu

Selecting the appropriate blockchain platform is a critical yet complex decision in supply chain management, given the evolving technological landscape and the absence of robust, adaptable evaluation frameworks. This study presents a comprehensive decision-making model using the Analytic Network Process (ANP) to guide platform selection by capturing the interdependencies among blockchain adoption enablers and evaluating the impact of alternative blockchain technologies. Drawing on an extensive literature review and expert input from industry and academia, key enablers—ranging from technical infrastructure to regulatory environment—are identified and structured into interrelated clusters. The ANP model incorporates these factors alongside leading platforms such as Ethereum Quorum and Hyperledger Fabric, allowing for a holistic comparison that reflects real-world complexity. Pairwise comparisons are conducted to derive priorities, and a Limit Matrix is computed using SuperDecisions software to synthesize results. Findings indicate that platform influence on enablers is often overlooked in existing models, limiting their applicability. Our framework addresses this gap, highlighting how different blockchain platforms affect criteria such as scalability, transparency, and integration potential. The study also considers dynamic conditions through sensitivity analysis, supporting more resilient and adaptable decision-making. Additionally, this research identifies emerging trends—particularly the growing role of artificial intelligence in blockchain integration and sustainability-focused developments, such as proof-of-stake consensus mechanisms. These insights pave the way for future studies to explore AI-enhanced blockchain strategies in supply chains. This work presents a novel, practical tool for decision-makers seeking to enhance supply chain transparency, efficiency, and resilience by selecting a tailored blockchain platform.

3 - Learning-Based Multi-Criteria Decision-Making Model for Site Selection Problems

Mahid Ahmed, University of Southern Mississippi, Hattiesburg, MS, United States, Ali Dogru, Chaoyang Zhang, Chao Meng

Choosing the right site for industrial facilities is essential for building efficient, profitable, and sustainable supply chains. Yet, finding the best location is no easy task. It involves navigating a mix of logistical, socio-economic, environmental, and climate-related factors. Traditional methods like Multi-Criteria Decision Making (MCDM) often depend on expert judgment, which can introduce bias, while exact optimization models focus heavily on proximity and struggle with computational limits as the number of site options grows. To tackle these challenges, we introduce a data-driven framework called the Learning-Based Multi-Criteria Decision Making (LB-MCDM) model. This approach blends machine learning, MCDM, and GIS-based spatial analysis to assess the suitability of potential sites in a more objective and scalable way. The model uses GIS raster analysis to score and rank candidate locations based on weights learned from ML algorithms. We apply this framework to a real-world case study in Mississippi, evaluating sawmill locations using nine key features: national land cover, distances to roads, rail lines, and urban areas, unemployment rate, terrain slope, precipitation, market revenue, and timber supply and demand. The model's predictions show strong alignment with where sawmills are currently located, validating its practical relevance. Beyond offering strategic insights, LB-MCDM can also assist traditional optimization models by reducing the number of candidate sites, making it easier to solve complex, NP-hard facility location problems.

4 - Decision Support System with a Multicriteria Approach for Prioritizing Credit Cards by Customers

VINICIUS TOMAZ, Technological Institute of Aeronautics, São Paulo, Brazil, ARSENIO GOMES NETO, Jonatas Almeida

The credit card market has become increasingly competitive in recent years in many countries and now offers a wide range of options to consumers. From this perspective, individuals trying to choose a credit card may find it difficult to compare the various perks and fees companies offer them. To assist this large group of people, a Decision Support System (DSS) was developed to allow each decision maker to tailor their criteria and identify which card is best suited to their needs, considering several options, using the SMARTER method. The solution proposed is scalable to support consumers around the world in wisely comparing different credit cards, which might stimulate

competitiveness among credit card operators and possibly lead to an improvement in the benefits offered to the public each operator wants to achieve. An example of this application is presented, analyzing 10 alternatives across 5 criteria. The model's solution indicated that "Credit Card 1" would be the most appropriate recommendation for this decision maker. Following the sensitivity analysis, the solution demonstrated strong robustness: after simulating one million scenarios to understand how the uncertainty introduced by the ROC approximation could affect the problem, the top-ranked alternative maintained its position in 97.48% of the cases.

1 - Natural Disasters and US Small Business Performance: Heterogeneous Effects

Julien Maire, Stanford University, Stanford, CA, United States, Alec Madayan, Kay Giesecke

We develop causal survival forest estimators for the impact of natural disasters on the behavior of small business borrowers in the United States. Using damage data from SHELDUS and loan-level performance data from the Small Business Administration for the period spanning 2008-2022, our Conditional Average Treatment Effects (CATE) estimates imply that the probability of charge-off increases by 8% after 18 months for the most impacted businesses, and the probability of prepayment decreases by 2% on average after 6 months for loans in affected areas. In addition, we find significant heterogeneity in treatment effects: small, short-term, non-franchise, out-of-state loans are the most vulnerable. We also find that these effects persist over time. Our results have important implications for the management of physical climate risk by policymakers and financial institutions.

2 - Physical Climate Risk for Mortgage Markets

Johannes Fuest, Stanford University, Stanford, CA, United States, Julien Maire, Kay Giesecke

We develop meta learning estimators for the causal impact of physical climate risk on the behavior of US residential mortgages and agency mortgage-backed securities (MBS). Using county-level loss data from SHELDUS, storm tracks from HURDAT2 and loan performance data from Fannie Mae and Freddie Mac, we estimate Conditional Average Treatment Effects (CATE) for loan-level transition probabilities for multiple time horizons. Our results show a significant uplift in severe delinquency probabilities for loans in zip-code areas experiencing damages greater than \$1,000 per capita, with heterogeneous effects driven by borrower credit score, debt-to-income ratio, original loan-to-value, and interest rate. We also observe heterogeneous effects on prepayment probabilities. We explore the implications of these findings for MBS markets.

3 - Portfolio Optimization for R&D Projects: a Real Options Dynamic Programming Approach

Ruixun Zhang, Peking University, Beijing, China, People's Republic of, Leonid Kogan, Andrew Lo, Qingyang Xu

We propose a dynamic strategy to optimize a portfolio of research and development (R&D) projects with correlated binary outcomes, which we call dynamic optimization of R&D options (DORADO). DORADO utilizes project correlation as a knowledge discovery mechanism in order to exercise real options with the information learned from previous outcomes to dynamically adjust future R&D plans. We focus on a class of R&D projects, known as long shots, that are difficult to manage using standard approaches. We derive the DORADO-optimal strategy and its corresponding financial value for these portfolios under batch testing, block correlation, and risk-sensitive objectives. DORADO generates an improved efficient frontier with a higher expected payoff and lower volatility than the comparable parallel development of these portfolios. Depending on investor preferences, the financial value of such an investment portfolio is maximized when the correlation between projects is either very low or very high, which reflects the tradeoff between the diversification gains at low correlations and the information value gained at high correlations. We provide an empirical example in the context of curative treatments for glioblastoma. Our results have important implications for managing highly correlated R&D projects that cannot be effectively diversified.

4 - Bitcoin Mining and Climate Damage

Steven Kou, Boston University, Boston, MA, United States, Min Dai, Shuaijie Qian, Ling Qin

We propose a tractable dynamic equilibrium model to study the impact of Bitcoin mining on climate damage. To incorporate miners' endogenous exit and entry with technology innovation, a critical modeling step is to draw on the idea of Ben Tahar, Soner, and Touzi (2010) to track the average operating costs rather than the exact operating costs, thus overcoming the difficulty of strong path-dependency incurred by the interaction among endogenous exit, entry, and technology innovation. The model can capture empirical co-movements of miners' computing power and mining revenue. The model predicts that Bitcoin mining is not economically sustainable in terms of long-term climate damage.

5 - Legislator Tweets About the Green Transition and the Returns of Green Versus Brown Stocks

Milind Goel, London Business School, London, United Kingdom

To study the impact of regulatory transition risk on firm value, we analyze stock returns around legislator tweets about climate change. Green stocks significantly outperform brown stocks in the one-to-ten-minute window around pro-transition tweets. The cumulative daily-average green-minus-brown portfolio return around pro-transition tweets is 6.9% higher than around anti-transition ones. For tweets that mention environmental regulations, the spread increases in the weeks leading to a congressional vote and disappears afterward. Our findings suggest that transition risk impacts the relative performance of green and brown stocks—at least partly—via a regulatory channel.

Office of Naval Research Program Review 1

Invited Session

ONR

Chair: David Phillips, Office of Naval Research, Arlington, VA, United States

1 - Algebraic, Geometric, and Topological Techniques for Optimization Problems from Machine Learning

Andrew Blumberg, Columbia University, New York, NY, United States

In this project we design and study machine learning methods for problems with rich geometric structure. For example, we consider methods that incorporate the symmetries from physical laws, optimal transport techniques for cell dynamics, and time series of random geometric objects. We apply these ideas to a wide range of problems, from fluid dynamics to genomic data sets.

2 - Topological Data Analysis and Optimization

John Carlsson, University of Southern California, Los Angeles, CA, United States

We present a framework that uses topological data analysis (TDA) to enhance optimization algorithms by identifying and exploiting coarse geometric features in solution landscapes. Our approach demonstrates how persistent homology can detect meaningful patterns in optimization problems across three key areas: (1) improving local search heuristics for discrete problems like the traveling salesman problem by using TDA to identify promising solution features that persist across multiple local optima,

(2) developing efficient dual quadratic programming methods for computing alpha complexes in high dimensions without requiring full Delaunay triangulation, and (3) applying filtered simplicial complexes to computer vision problems like image correspondence to classify and avoid problematic local minima caused by repeated patterns. By focusing on topological invariants, our methods provide robust guidance for optimization algorithms, helping them navigate complex solution spaces more effectively and avoid getting trapped in poor local optima that arise from geometric artifacts in the problem structure.

3 - Data-Aware Guarantees for Mathematical Optimization and Learning

Mojtaba Soltanalian, University of Illinois Chicago, Chicago, IL, United States

As AI and optimization systems become increasingly central to high-stakes decision-making, a pressing question arises: *How can we know if a model is truly doing its job?* This talk introduces MERIT—a framework that reimagines optimization by iteratively solving a sequence of well-posed surrogate problems, each bringing us measurably closer to the true solution. MERIT offers not just solutions, but certifiable progress toward global optimality.

We begin with MERIT's impact on sparse signal recovery, where we move beyond classical regularization-based approaches. By embracing judicious overparameterization, we derive data-informed reliability metrics. These results offer a fresh lens on sparsity-driven inference; especially under noisy or uncertain conditions.

We then pivot to deep learning, where MERIT enables real-time certification of training progress. We particularly focus on the Yeganegi–Eamaz–Soltanalian (YES) training bounds: a principled family of training guarantees that provide a simple answer to a fundamental question—*Has this network been properly trained by the data?* YES bounds are data-aware, structure-aware, and offer actionable insights into the training process.

Together, these advances form a new toolbox for designing models that *know how well they've been trained* and *how much they can be trusted*.

4 - Scaling MINLPs via Branch-and-Bound and First Order Methods with Applications to Structured Statistical Learning

Rahul Mazumder, MIT, Cambridge, MA, United States

Mixed integer programming (MIP) especially, mixed integer nonlinear programming (MINLP), is a promising tool for modeling and solving key statistics/machine learning (ML) problems that admit a combinatorial description. Several statistical estimators that can be expressed as solutions to MIP problems are known to enjoy optimal statistical properties. However, they lead to computational challenges. I will discuss an approach based on an integrated branch-and-bound and first-order method framework to address a family of problems in statistics/machine learning. In a variety of learning instances, under mild statistical modeling assumptions, the underlying MIP can be simplified into another MIP which is empirically "simpler" to solve (example, MISDP can be simplified into a MIQP). The algorithms we discuss are all open-sourced.

Human–AI Collaboration for Smarter Business

Invited Session

eBusiness

Chair: Tian Lu, Arizona State University, Tempe, AZ, United States

1 - Responsible Engagement: Organizational Strategy to Counteract Agency Reversal

Thomas Ware, Arizona State University, Tempe, AZ, United States

This study examines the challenge of agency reversal in AI-assisted decision-making, where human decision-makers become passive executors of algorithmic recommendations rather than active evaluators. Through a field experiment in the microlending sector, we introduce the concept of responsible engagement (RE) as a cognitive mechanism designed to counteract agency reversal without sacrificing the efficiency benefits of AI. Drawing on Work System Theory, we implement a behavioral nudge that positions decision-makers as the primary authority in the AI-assisted process. Our findings demonstrate that evaluators exposed to RE exhibit deeper information processing, more discerning integration of AI recommendations, and stronger perceptions of personal responsibility. Notably, these improvements in human agency do not come at the cost of decision efficacy or increased cognitive burden. The study contributes to our understanding of how socio-technical design can mitigate agency reversal while preserving the instrumental value of AI in operational decision-making, offering practical insights for responsible AI governance in financial and other organizational contexts.

2 - Expertise and Inevitable Errors of Algorithms

Yu Gao, Peking University, Beijing, China, People's Republic of

Growing evidence shows that experts tend to be reluctant to use artificial intelligence (AI)–based decision-support systems. This algorithm aversion poses a challenge to widespread adoption of AI decision support, given the importance of these experts' role in the diffusion process. We introduce a framework emphasizing AI's and decision makers' ability in making stable predictions. In a series of experiments, we explore how individuals, classified as "experts" and "laypeople" based on an exogenous manipulation of their prediction stability, respond to the inevitable errors made by AI. We find that experts significantly decrease reliance on AI after encountering single-instance errors, despite knowledge of its overall accuracy. Conversely, they do not increase reliance even when AI outperforms their predictions. This asymmetric response of experts persists across different tasks, even those beyond their expertise. This study advances our understanding of the emergence of algorithm aversion in decision makers with high expertise, providing valuable insights for improving AI decision-support system acceptance.

3 - Human OR Robot: Evidence from Last-Mile Delivery Service

Baorui Li, Naveen Jindal School of Management, University of Texas at Dallas, Richardson, TX, United States, Xincheng Ma, Brian Han, Daizhong Tang, Lei Fu

The increasing integration of service robots into offline environments has ushered in a transitional phase where human and robot service providers co-exist. Although prior research has explored consumer acceptance of service robots, little is known about how contextual features and underlying mechanisms shape consumer's choice in real-world settings. To address this gap, we conduct an empirical study on consumer's choice of human versus robot service, analyzing 236,776 package-level choice records from Alibaba's last-mile delivery stations. We propose that privacy sensitivity, product value, and environmental complexity elicit distinct psychological mechanisms. Our findings reveal that consumers are significantly more likely to choose robot delivery for privacy-sensitive packages (11.11%, $p < 0.001$) and high-value products (0.86% per 1% increase in value, $p < 0.001$), but prefer human couriers under adverse weather conditions (1.68%, $p < 0.001$). These findings underscore that delivery choices are shaped not only by functional considerations but also by psychological concerns, highlighting the need for context-aware service design that aligns strategies with consumer perceptions of privacy, risk, and trust.

4 - Market Intelligence and Complementors' Product Strategies: a Large-Scale Empirical Study of An E-Commerce Platform

Bowen Lou, University of Southern California, Los Angeles, CA, United States, Zhe Yuan, Tianshu Sun, Lu Fang

How does enhanced market intelligence, facilitated by platform-provided tools, shape complementors' product strategies? Collaborating with a leading e-commerce platform, we analyze over 40,000 sellers and a policy change that expanded access to a market intelligence tool. Our analysis shows that greater information access leads to more new product launches, shorter product life cycles, and higher prices for new offerings. Sellers primarily introduce products with novel attributes outside their existing portfolio, often integrating features observed from peer sellers through the tool. This expands their search space for innovation while driving convergence in customer bases. Overall, we highlight how enhanced engagement with market intelligence influences complementors' strategies through imitation, differentiation, and pricing adjustments—offering important implications for platform governance and policy.

5 - Crowding the Machine: How Does Widespread Large Language Model Adoption Reshape Profile Screening

Tian Lu, Arizona State University, Tempe, AZ, United States

The rapid rise of large language models (LLMs) has democratized professional-quality writing, enabling widespread use for tasks like profile polishing. This creates a strategic dilemma for decision platforms: should they encourage LLM use to enhance applicant communication or restrict it to preserve the effectiveness of human evaluation? The surge in LLM tutorials and services has intensified this tension. While LLMs improve surface-level writing, their adoption in high-stakes contexts—such as recruitment, admissions, and financial services—raises concerns that polished but homogenized profiles could obscure evaluators' ability to identify high-quality candidates. This study investigates crowd-level LLM use in microloan credit risk evaluation. Using a mixed-methods approach, we examine how borrowers' use of LLMs to enhance loan statements affects human evaluators' screening behavior and decision outcomes. Our findings show a non-monotonic relationship: as LLM use increases, evaluators face greater cognitive burden from diluted signals, shifting effort allocation and reducing decision quality. Building on these insights, we use analytical modeling to assess strategies for microloan platforms—whether to provide LLM toolkits to applicants or deploy LLM detectors during screening—and explore broader implications of widespread LLM use. This research contributes by revealing unintended consequences of LLM adoption in evaluative settings and identifying conditions that amplify these effects. It offers practical guidance for managing AI-human interaction in sensitive decision-making environments.

1 - Towards Nature-Inspired Design and Control of Autonomous Multi-Agent Systems

Anahita Jain, The University of Texas at Austin, Austin, TX, United States, Husni Idris, John-Paul Clarke

Autonomous vehicle operations are expected to grow in the skies over the next decade, beginning with applications such as firefighting and cargo delivery, and expanding to passenger transport. These vehicles are expected to interact and integrate with other traffic within the airspace. For scalability, this airspace of the future will be a collective system of autonomous vehicles, where each vehicle makes increasingly independent decisions.

The successful implementation of these decentralized, autonomous, collective multi-vehicle systems can benefit from understanding existing multi-agent systems, such as colonies of ants or schools of fish. This helps us identify the *characteristics* or *behaviors* that make these systems “good”, and subsequently identify the metrics that *quantify* these characteristics. Further, these metrics can be leveraged for the design of agent behaviors and coordination mechanisms to *achieve* these desired traits in the collective autonomous multi-agent system.

We hypothesize that at low densities, “self-separation” by aircraft maintaining minimum separation distances is sufficient to ensure safety. As density increases, “self-organization” becomes necessary for maintaining efficiency. This is achieved by enabling aircraft to independently and dynamically create airspace order when beneficial, by adjusting the degree to which they follow other airspace traffic. At even higher densities, “self-limitation”- using metrics such as trajectory flexibility- becomes necessary to ensure aircraft have enough room to maneuver to mitigate the effects of uncertainties and perturbations.

In this talk, we will explore each of these self-behaviors and their interrelationships, using the nature-inspired models and capabilities we developed to enable them in aviation and other multi-agent systems.

2 - Physics-Informed Machine Learning for Enhanced Traffic Control: from Megavandertest to Neural Finite Volume Methods

Zhe Fu, UC Berkeley, Berkeley, CA, United States

Strategically controlling a small number of “leader” vehicles can significantly enhance traffic flow, improving efficiency, fuel economy, and driver comfort for the entire traffic system with minimal intervention. This was validated in the MegaVanderTest, a large-scale field experiment involving 100 autonomous vehicles (AVs) operating in mixed autonomy traffic. We designed both model-based and machine learning-driven control strategies for the AVs to improve traffic congestion and reduce the system-wide fuel consumption by over 10%.

However, the effectiveness of these control strategies heavily relies on accurate traffic state predictions and reliable communication. To address these challenges, we developed the Neural Finite Volume Method (NFVM), a physics-informed machine learning framework that integrates neural networks with physics-based models to solve hyperbolic partial differential equations (PDEs). NFVM achieves high predictive accuracy while maintaining key physical principles such as conservation laws and entropy conditions, making it well-suited to capturing complex traffic phenomena like shocks and stop-and-go waves. NFVM not only outperforms traditional finite volume solvers in accuracy but does so with comparable computational cost. It also offers structural flexibility, enabling multi-timestep inputs and the ability to generalize from PDE-synthetic data to experimental field data.

By embedding NFVM as the traffic state estimation layer within the AV control stack, we further enhance the performance and robustness of our control strategies.

3 - UAV Search and Routing Planning in a Disaster Area

Nastaran Olad zad-Abbasabady, University at Buffalo-SUNY, Amherst, NY, United States, Esther Jose, Rajan Batta, Miguel Lejeune

The goal of this work is to identify the best Search and Routing Planning (SRP) for an Unmanned Aerial Vehicle (UAV) to maximize the total number of casualties detected in a disaster-affected area within a limited mission duration. First, we introduce a Mixed-Integer Nonlinear Programming (MINLP) formulation with a nonlinear objective function. To linearize the objective function, additional assumptions and constraints are imposed, resulting in a Mixed-Integer Linear Programming (MILP) approximation of the original problem. We then describe an exact solution method and a hybrid heuristic that yield higher-quality solutions. In addition, a clustering-based heuristic is proposed to handle larger problem instances. The framework is extended to account for uncertainty in casualty estimates and coordination among multiple UAVs. The effectiveness and computational performance of the proposed methods are validated through a comprehensive set of experiments. Finally, a case study inspired by the 2023 Turkey-Syria earthquakes demonstrates the real-world applicability of our approach to time-critical post-disaster search operations.

4 - Robotic Mobile Fulfillment Systems: Strategies for Pod Selection and Scheduling

Kerim U. Kizil, Texas A&M University, College Station, TX, United States, Chelliah Sriskandarajah, Jon Stauffer

Robotic mobile fulfillment (RMF) systems automate storage and transportation within fulfillment centers while still relying on human pickers. We focus on two performance metrics in these systems, aiming to minimize overall completion time (OCT) as the primary objective and the number of required robots (NRR) as a secondary objective. We investigate two interrelated operational problems influencing these metrics: (i) pod selection and (ii) pod scheduling. We first explore the pod scheduling problem independently, providing theoretical results. This stand-alone problem is NP-hard with at least two pickers when minimizing OCT and remains NP-hard with even one picker when minimizing NRR. The NRR objective introduces a novel optimization problem structure, contributing to scheduling theory. We demonstrate that a simple but effective scheduling rule is asymptotically optimal for minimizing OCT with multiple pickers. For NRR minimization with a single picker, we derive theoretical performance bounds for two sequencing rules. When incorporating the pod selection problem, we focus on two approaches: (i) sequential and (ii) integrated pod selection and scheduling. The sequential approach handles pod selection first, then pod scheduling, while the integrated approach addresses both problems simultaneously within a single formulation to minimize OCT. Computational experiments using e-commerce order data reveal that the sequential approach achieves

significantly faster computation times, with a mean OCT similar to that of the integrated approach. We also find that our sequencing rules can reduce mean NRR by 13% to 28% without affecting OCT, compared to the case where no such rules are used.

1 - Regulation of Algorithmic Collusion from Data

Chenhao Zhang, Northwestern University, Evanston, IL, United States

Algorithms are increasingly being used to price goods and services in competitive markets. Many recent papers have shown that in various settings, some configurations of certain pricing algorithms can find and maintain supra-competitive prices from repeated market interactions. We give a definition of plausible algorithmic non-collusion for pricing algorithms. On one hand, the definition allows sellers to utilize useful side information that may be correlated with supply and demand. On the other hand, it allows a regulator to empirically audit algorithms by applying a statistical test to the data they collect. We provide an analysis of the statistical complexity of such an audit, i.e., how much data is sufficient for the test of non-collusion to be accurate. We further discuss the unrelaxability of the definition even when there is no side information, as well as the role of the regulator's knowledge of the seller's cost in the audit.

2 - Decision-Making Under Uncertainty: Improving Multi-Armed Bandits and Pessimism Traps

Kavya Ravichandran, Toyota Technological Institute at Chicago, Chicago, IL, United States

We study decision-making under uncertainty in two settings: first, we give nearly-tight upper and lower bounds for the improving multi-armed bandits problem. An instance of this problem has k arms, each of whose reward function is a concave and increasing function of the number of times that arm has been pulled so far. We show that for any randomized online algorithm, there exists an instance on which it must suffer at least an $\Omega(\sqrt{k})$ approximation factor relative to the optimal reward. We then provide a randomized online algorithm that guarantees an $O(\sqrt{k})$ approximation factor, if it is told the maximum reward achievable by the optimal arm in advance and $O(\sqrt{k} \log k)$ approximation if it must estimate that quantity. In the second work, we model pessimism traps -- a phenomenon studied by philosophers in which agents are influenced by their communities to not engage in ambitious ends. Adapting an opinion dynamics model to capture the key facets of pessimism traps, we show how easily these traps develop. In order to sustainably shift a community out of pessimism, we develop a targeted subsidy scheme. We then extend such an intervention to a setting where there are many different communities for whom different actions are considered optimistic, showing that even with limited information about the communities, a centralized agency can help shift all of them toward optimism.

3 - Boosting in-Context Learning in LLMs Through the Lens of Classical Supervised Learning

Korel Gundem, George Washington University, Washington, DC, United States, Juncheng Dong, Dennis Zhang, Vahid Tarokh, Zhengling Qi

In-Context Learning (ICL) allows Large Language Models (LLM) to adapt to new tasks with just a few examples, but their predictions often suffer from systematic biases, leading to unstable performances in classification. While calibration techniques are proposed to mitigate these biases, we show that, in the logit space, many of these methods are equivalent to merely shifting the LLM's decision boundary without having the ability to alter its orientation. This proves inadequate when biases cause the LLM to be severely misdirected. To address these limitations and provide a unifying framework, we propose Supervised Calibration (SC), a loss-minimization based framework, which learns an optimal, per-class affine transformation of LLM's predictive probabilities in the logit space without requiring external data beyond the context. By using a more expressive functional class, SC not only subsumes many existing calibration methods in ICL as special cases but also enables the ability of altering and even completely reversing the orientation of the LLM's decision boundary. Furthermore, SC's loss-based nature facilitates the seamless integration of two purpose-built regularization techniques—context-invariance and directional trust-region regularizers. The former is designed to tackle the instability issue in ICL, while the latter is to control the degree of calibration. Finally, SC delivers state-of-the-art performance over calibration baselines in the 4-shot, 8-shot, and 16-shot settings across all nine datasets for Mistral-7B-Instruct-v0.3, Llama-2-7B-chat, and Qwen2-7B-Instruct.

4 - Generative AI and the Division of Labor in Knowledge Work

Maximilian Schaefer, Institut Mines-Télécom Business School, Evry, France, Vincent Lefrere

This study investigates the impact of Large Language Models (LLMs), such as GitHub Copilot, on software development practices. We construct a longitudinal panel dataset of GitHub developers from 2011 to 2025 using event-level data and API-enriched metadata. The dataset captures detailed information on code contributions, collaboration patterns, and developer profiles. Our research focuses on two main questions: (1) how LLM adoption influences productivity, code reuse, and team structure, and (2) how the presence of AI-generated code can be identified using watermarking and machine learning-based detection methods. By linking developer behavior to the diffusion of generative AI tools, we contribute to a broader understanding of how automation transforms knowledge work and collaborative production at scale.

1 - Feedback Design and Equilibrium Knowledge-Sharing

Xinbo Wang, National University of Singapore, Singapore, Singapore, Nan Chen

Feedback systems are widely used by digital platforms. We study how feedback design shapes equilibrium content provision in the context of Stack Overflow. Using a regression discontinuity design based on answer timing, we show that competition shapes feedback and influences contribution. We develop and estimate an empirical model that links feedback design to equilibrium outcomes among heterogeneous contributors. The model allows the platform to continuously adjust *leniency* (the tendency to give positive feedback) and *harshness* (the tendency to give negative feedback). We decompose feedback's impact into a direct effect on individual contributors and an indirect competitive effect. We find that although a contributor favors more leniency and less harshness when considered alone, she may prefer less leniency and higher harshness in equilibrium. This reversal arises from competition and depends on user quality, with higher-quality contributors being more likely to alter their preferences under equilibrium incentives. We further show how the platform's targeted quality levels, its ability to distinguish contributor quality, and the distribution of contributor skill shape competition and inform optimal feedback design. Finally, we consider the case of endogenous feedback preferences, where contributors' valuations of feedback depend on the equilibrium quality induced by the mechanism.

2 - How Platform Transparency Shapes Provider Choices: Evidence from a Natural Experiment on Lyft

Rubing Li, New York University, New York, NY, United States

In February 2024, Lyft introduced a policy guaranteeing drivers at least 70% of rider payments while also increasing per-ride earnings transparency. The rollout of this policy was staggered, first introduced in "major markets" that were more urban, and provided a natural experiment to assess how platform transparency and earnings guarantees affect ridesharing availability, driver engagement and rider satisfaction. Using trip-level data from over 47 million rides in a major urban market and its neighboring suburban markets across six months, we applied dynamic staggered difference-in-differences models to measure the causal effects of these platform design changes on supply- and demand-side outcomes, and ensuing ridesharing performance. We show that the design change led to substantial changes in driver engagement, with separate effects from the guarantee and the transparency. Drivers increased their working hours and utilization, leading to more completed trips and higher per-hour

and per-trip earnings. These effects were strongest for drivers with lower pre-policy earnings and greater income uncertainty. We unpack the economic mechanism by which increased supply also had a positive spillover on demand, boosting rider app engagement and booking conversions and lowering wait times in high demand areas. We also provide some evidence that points to platform transparency potentially leading to unintended strategic driver behavior.

3 - Sharing the Spotlight: the Impact of a Credit System on Creator Collaboration Dynamics in An Online Platform

Yue Zhang, The Hong Kong University of Science and Technology, Hong Kong, China, People's Republic of

Collaboration yields high-quality outcomes in business, research, and online content creation. However, collaboration can be hindered when individual contributions go unrecognized. In this paper, we study how a formal credit system in an online video platform affects creators' collaboration dynamics and examine how these effects vary across creators of different popularity levels. We find that implementing the credit system significantly increases the likelihood that a video is produced collaboratively, as well as the engagement metrics of videos that adopt the system. We further demonstrate that the system's impact increases with a creator's popularity but has little effect on less popular creators. This raises concerns about unintended consequences, as the credit system may exacerbate attention disparities within the creator community. Additionally, we analyze how the credit system influences collaboration patterns between creators and their collaborators. We find that creators are more likely to collaborate with creators of similar popularity, direct competitors, and previous collaborators. Our study contributes theoretically by elucidating the interplay among credit attribution, collaboration, and competition on online platforms, and offers practical insights for platform owners to balance the benefits and costs of implementing a formal credit system.

4 - Calibrated Coarsening: Designing Information for AI-Assisted Decisions

Ruru Hoong, Harvard Business School / Harvard Economics, Cambridge, MA, United States

Artificial intelligence (AI) signals are increasingly deployed as human decision-making aids across many critical applications, but human cognitive biases can prevent them from improving outcomes. We propose *calibrated coarsening*—partitioning the signal space into fewer cells at optimised thresholds—as a way to improve decision-making outcomes while (i) keeping humans in the loop, (ii) modifying signals without deception, and (iii) adapting flexibly to various cognitive biases and decision-making contexts. Within an optimal information disclosure framework, we derive the approximately-optimal universal coarsened policy for settings where the designer does not observe the decision-maker's information. We then empirically demonstrate in a randomised experiment involving loan specialists that coarsening AI signals at the theory-derived threshold significantly improves decision-making outcomes, over both the human-only (based solely on the loan application) and continuous AI (assisted with uncoarsened AI risk-score) benchmarks. We uncover substantial decision heterogeneity amongst loan officers, and use a Bayesian hierarchical model to personalise coarsening policies, which can further improve outcomes as past data become available.

1 - Ranking Crop Cultivars Using Stochastic Dominance

Shayan Tohidi, Iowa State University, Ames, IA, United States, Sigurdur Olafsson

Sustainability of food production relies on crop cultivars that perform well under a range of environmental conditions. This requires comparing crop cultivars as random prospects, where the uncertainty is due to the environment. Stochastic Dominance (SD) is a classical way of comparing and ranking random prospects, which accounts for the outcome and risk. The goal is to find those with Maximum Expected Utility (MEU), and the SD rules guarantee the results, e.g., the first and second order stochastic dominance do it for all and risk-averse decision makers, respectively. While these methods are important, they may not apply in practice due to existing extreme utilities that enlarge the efficient set. Almost Stochastic Dominance (ASD) has been proposed to eliminate extreme utility functions and be acceptable to most decision makers. Although it shrinks the size of the efficient set, its magnitude depends on a tunable parameter ϵ . Moreover, the dominant prospect always should have a higher expected value, even if that margin is small. This makes ASD less applicable in certain real-world problems, such as crop cultivar selection, where it may be sensible to prefer a more stable cultivar to a cultivar with slightly higher expected yield. We propose a new heuristic method that does not require tunable parameters and has no constraints on the expected value. The relationship with other SD and ASD methods and the special cases is described, and the method is applied to a crop selection case study.

2 - Optimizing Distributed Manufacturing of Biomass-Based Chemicals with Electrochemistry and Renewable Energy

Motahareh Kashanian, Iowa State University, Ames, IA, United States

The push for sustainable chemical manufacturing has sparked interest in distributed production systems powered by renewable energy. This talk presents a multi-study framework for optimizing the distributed manufacturing of biomass-based chemicals, focusing on electrochemical processes as a greener alternative to traditional methods. We explore the integration of local renewable energy sources, solar and wind, into electrochemical conversion systems, aiming to reduce greenhouse gas emissions and improve the economic viability of decentralized production.

Our approach combines supply chain design, techno-economic analysis, and uncertainty modeling to evaluate the feasibility of these systems at scale. Using mixed-integer linear programming and stochastic programming, we model the trade-offs between centralized and distributed production under various policy, technical, and environmental scenarios. We also investigate how process scale, renewable availability, and the social cost of carbon influence facility location, size, and overall system performance.

Results highlight the role of modular, renewable-powered systems in lowering emissions while maintaining cost-effectiveness, especially under dynamic energy and policy conditions. The framework is demonstrated through case studies for the production of trans-3-hexenedioic acid (t3HDA), offering insights into real-world applicability and pathways for broader deployment.

3 - Systems Modeling and Analysis for a Sustainable Material Future

Sidi Deng, University of Michigan, Ann Arbor, MI, United States, Daniel Cooper, Yuehwen Yih, John Sutherland

Materials are the building blocks of industrial society, flowing through supply chains that represent complex, interconnected networks. Given this, material sustainability is inherently a systemic challenge that calls for cross-cutting, macro-oriented strategies grounded in systems thinking. This talk presents an interdisciplinary research roadmap for fostering a sustainable, material-centered industrial landscape through the lens of system modeling and analysis. Central to this job talk is how model-based virtual representations of industrial ecosystems, combined with data-driven approaches, inform decision-making to advance key sustainability dimensions, including material circularity, economic feasibility, environmental performance, and supply chain resilience. The talk opens by highlighting the presenter's Ph.D. work on advancing the circular economy of critical materials essential to the clean energy transition, incorporating and synergizing a diverse set of computational tools, including simulation, machine learning, network analysis, and system dynamics. The middle section highlights the presenter's current research on decarbonizing the aluminum industry through the modeling and simulation of supply chains and technology pathways. At its core is an agent-based computational engine that drives Monte Carlo simulation, dynamic material flow analysis, life cycle assessment, and risk-informed scenario analysis using experimental design. The job talk concludes with the presenter's future vision for navigating complex industrial systems, highlighting opportunities to integrate geospatial analysis, physics-informed machine learning, and digital twins. Through his research, the presenter seeks to drive the transition toward a smart and resilient industrial landscape rooted in sustainable material systems.

4 - It's Still Good! Expiration Dates and Food Waste

Parisa Shahsavand, The University of Texas at Dallas, Richardson, TX, United States, Dorothee Honhon, Iva Rashkova

This paper examines how expiration dates influence food waste and consumer behavior. In the United States, expiration dates (except for infant formula) are not federally regulated and are typically intended to reflect product quality, not safety. However, many consumers misinterpret them, leading to premature disposal of still-edible food and contributing substantially to household food waste. We model a food producer that determines the shelf life and production cycle of a perishable product and analyze consumer behavior along two dimensions: whether they consider expiration dates at the time of purchase and whether they consider them when consuming products at home. Our results show that when consumers ignore expiration dates during purchase, producers tend to set both the shelf life and production frequency equal to the biological life of the product, resulting in higher absolute waste at the consumer level. Most notably, we find that food waste is minimized when consumers pay attention to expiration dates while shopping but are willing to consume products past the expiration date at home, as long as the product remains palatable. This consumer behavior allows for informed purchasing and reduced unnecessary disposal. Our findings suggest that expiration dates, when properly understood and used, can support rather than hinder waste reduction efforts. Consumer education that frames expiration dates as indicators of quality rather than safety can promote more sustainable consumption behavior and better alignment between producer decisions and societal waste reduction goals.

Chair: Anyi Li, Auburn University, Auburn, AL, 36830, United States

1 - Physics- and Shape-Constrained Data Science Methods with Applications in Materials and Industrial Informatics

Yating Fang, Department of Industrial and Systems Engineering, Rutgers University, Piscataway, NJ, United States, Qianqian Zhao, Ryan B. Sills, Ahmed Aziz Ezzat

This talk highlights my dissertation research on scientific machine learning for materials and industrial systems. I will present a shape-constrained method that introduces, for the first time, monotonicity constraints to the mixture of experts framework (a prevalent ensemble learning method), with applications in materials failure and asset management. This is followed by an overview of my related research and educational accomplishments and future agenda.

2 - Advancing Additive Manufacturing with Physics Informed Deep Learning: Geopipn for Fast Thermal Prediction in Unseen Part Geometries

Amirul Islam Saimon, Virginia Tech, Blacksburg, VA, United States, Raghav Gnanasambandam, Zhenyu Kong

This talk will briefly review current progress and key challenges in applying deep learning to additive manufacturing. It will then introduce Geometry-Aware Physics Informed PointNet (GeoPIPn), a novel deep learning-based fast prediction model for solving Partial Differential Equations (PDE) across unseen geometries. Thermal distributions in additive manufacturing (AM) parts, governed by diffusion PDEs, are key to ensuring material quality, microstructure uniformity, and dimensional accuracy. Existing thermal modeling relies on Finite Element Method (FEM), which is computationally expensive for fast-paced, iterative geometric design. Furthermore, these methods are tailored to a specific part geometry, requiring rerunning for each new geometry, making them inefficient for designs that change frequently. Once trained, our GeoPIPn can predict the thermal distribution for a new part geometry very quickly without rerunning the FEM simulations. In the case studies, we demonstrate the superior performance of our GeoPIPn over state-of-the-art benchmark methods. Remarkably, GeoPIPn is the first PINN-based model focusing on thermal modeling in AM for new part geometries with improved performance. Consequently, it offers a powerful solution for fast and accurate AM design.

3 - Process-Driven Machine Learning for Intelligent and Collaborative Fatigue Modeling in Additive Manufacturing

Anyi Li, Auburn University, Auburn, AL, United States, Jia Liu

Understanding the fatigue behavior and accurately predicting the fatigue life of laser power bed fusion (L-PBF) parts remains a pressing challenge due to complex failure mechanisms, time-consuming tests, and limited fatigue data. My research tackles these challenges through two key directions: (1) developing a physics-informed, nondestructive fatigue life prediction framework, and (2) designing a generalized, privacy-preserving federated learning model that supports cross-organizational collaboration in heterogeneous and data-scarce environments.

The first contribution introduces a Multimodal Transfer Learning (MMTL) framework to understand process-defect-fatigue relationships in L-PBF parts via a hierarchical graph-based representation. MMTL leverages a pre-trained model with abundant process and defect data in the source task to predict fatigue life nondestructively with limited fatigue test data in the target task. This work demonstrates the feasibility of nondestructive fatigue life prediction even with limited labeled data, offering a scalable and interpretable solution to enhance AM reliability.

The second presents a personalized federated learning framework that allows multiple manufacturers to collaboratively train predictive models without sharing their raw data. To address data heterogeneity, especially clients with differing feature sets-we incorporate domain adaptation and statistical alignment techniques to share knowledge from feature-rich clients to those with missing features. This framework enables small and medium-sized manufacturers to benefit from collective intelligence while maintaining data privacy and operational independence.

1 - Optimal Subsidies for Carbon Capture: a Stackelberg Game Analysis

Connor Colombe, University of Texas at Austin, Austin, TX, United States

Model-based scenarios for achieving decarbonization tend to envision significant deployment of carbon capture (CC) technologies. In the United States, the federal government subsidizes CC through its 45Q tax credits. In this paper, we develop and analyze a Stackelberg game model featuring a social-welfare-maximizing government and a profit-maximizing firm. The government sets the level of a CC subsidy and the firm responds by jointly deciding whether or not to invest in CC technology and on its production level. In the case where the government has perfect information about the firm's parameters, we analytically derive the optimal CC subsidy and establish the conditions under which inducing the firm to invest in CC will actually increase carbon emissions. We then consider an extension where the firm's CC investment cost is uncertain from the government's perspective. In this case, we show that uncertainty can situationally raise or lower the optimal subsidy. Lastly, we apply our model to a numerical case study of a coal power plant and estimate optimal subsidy values. We find that the current subsidy level of \$85 Mt/CO₂ is likely a sufficient subsidy level to incentivize CC adoption and that the value may be approximately social welfare maximizing. In addition, we find that uncertainty may cause the Government to overspend \$1.4 billion over a ten year period when compared to the subsidy offered under perfect information. Furthermore, we find that the subsidy value our model predicts led to an 83% reduction in CO₂ emissions when compared to the no-subsidy equilibrium value.

2 - Optimal Policy Portfolios to Promote Carbon Capture

Abdullah Albeladi, The University of Texas at Austin, Austin, TX, United States, Benjamin Leibowicz

Carbon capture (CC) technologies are projected to play important roles in deep decarbonization pathways, yet their deployment to date has been limited. Current policy incentives for CC primarily take the form of flow subsidies per ton of carbon dioxide (CO₂) captured, as in the 45Q tax credits in the U.S. In this paper, we investigate whether a policy portfolio consisting of multiple instruments -- a flow subsidy, an upfront investment subsidy, and an emissions penalty -- could spur CC adoption, reduce net CO₂ emissions, and contain government costs more effectively than the prevailing flow-subsidy-only approach. We formulate a Stackelberg game model in which the government sets the levels of these policy instruments to maximize social welfare, anticipating the reactions of heterogeneous firms who choose whether to adopt CC, their production levels, and CO₂ capture rates to maximize profits. After deriving analytical solutions to the firms' problems and for the share of firms who adopt CC, we apply the model to a numerical case study of natural gas-fired power plants. We find that the optimal policy design employs all three instruments and yields 52% higher social welfare than a flow subsidy alone. Our results clarify the primary role that each instrument should fulfill in the optimal portfolio: the upfront subsidy induces firms to install CC, the flow subsidy covers baseline CC operating costs, and the emissions penalty incentivizes high CO₂ capture rates.

3 - Carbon Capture and the Power Sector: Health and Environmental Outcomes of US Policies

Paola Furlanetto, UMass Amherst, Amherst, MA, United States, Erin Baker, Nexus Attiogbe, Michael Ash

Recent U.S. policies—such as the Inflation Reduction Act's 45Q tax credit and the EPA's CO₂ Performance Standards for fossil fuel power plants—seek to accelerate carbon capture (CC) deployment in the power sector. This study explores the interactions between these policies, the EPA's Good Neighbor rule, and a hypothetical carbon tax across diverse technical and geographic scenarios. Using a power flow model of a stylized three-node grid, we simulate investment decisions in CC retrofits and new generation capacity, while tracking emissions of both CO₂ and harmful co-pollutants (NO_x, SO_x, PM_{2.5}, NH₃ and VOCs).

Our analysis reveals that while CC incentives can reduce greenhouse gas emissions, they may also unintentionally promote continued fossil fuel use and delay renewable energy deployment. In some scenarios, co-pollutant emissions and associated health damages increase, though these can be mitigated through complementary policies that directly regulate co-pollutants. These findings highlight the need for integrated policy design that considers not only carbon outcomes but also public health. As the U.S. navigates a rapidly evolving climate policy landscape, our results underscore the importance of aligning decarbonization strategies with broader societal goals.

4 - Evaluating Payments for Ecosystem Services: Cover Cropping and Water Quality in the Midwest

Shuo Yu, University of California, Berkeley, Berkeley, CA, United States

Agricultural runoff significantly contributes to nutrient water pollution, leading to harmful environmental and economic consequences. Cover cropping (CC), the practice of planting non-cash crops during off-seasons, has emerged as a promising conservation strategy to mitigate these impacts. Payment for ecosystem services programs, such as the USDA's Environmental Quality Incentives Program (EQIP), have increasingly supported CC adoption through incentives. This study evaluates the social value of EQIP in enhancing water quality by examining its impact on CC adoption and the subsequent reduction in water pollution in the Midwest. Leveraging a unique 17-year, satellite-derived dataset on plot-level CC adoption and granular harmonized water quality metrics, we find that a one percentage point increase in upstream CC adoption reduces total nitrogen in surface water by 0.9%. An event-study analysis of EQIP's Mississippi River Basin Initiative shows an initial 8.7 percentage point increase in CC adoption, with the impact diminishing over time. Overall, EQIP's CC practices recover 48% of their implementation costs through reductions in nitrogen pollution under conservative assumptions, suggesting partial but significant economic returns via water quality improvements.

Intelligent and Safe Autonomy for Aerial Systems

Invited Session

Air Transportation Section

Chair: Yuwei Wu, University of Pennsylvania, Philadelphia, PA, United States

1 - Distributed Optimization for Safe Multi-Agent Aerial Autonomy

Matthew Hale, Georgia Institute of Technology, Atlanta, GA, United States

The future of aerial transportation is likely to involve large numbers of vehicles that must safely navigate, perhaps in close proximity. Close proximity means that collision avoidance is of paramount importance, yet the presence of large numbers of vehicles means that centralized planning may be computationally inefficient or outright infeasible. Therefore, in this talk I will present a decentralized framework for safe multi-agent aerial autonomy. First I will present recent developments on an optimization algorithm for safe, decentralized motion planning that computes optimal paths while obeying all collision avoidance constraints. This algorithm is decentralized by design, and I will show that it is robust to asynchrony in the sense that agents can asynchronously compute and communicate, and they will still find a safe, optimal motion plan. Then I will demonstrate the results of such plans experimentally on aerial vehicles. These experiments show the success of this framework in practice, and they demonstrate that even computationally constrained, lightweight, and low-power aerial agents can reliably compute safe, optimal motion plans.

2 - Llm-Based End-to-End Flight Planning with Integrated Multimodal Review

Amin Tabrizian, George Washington University, Washington, DC, United States

We propose a novel end-to-end framework for automated flight planning that leverages large language models (LLMs) in both the planning and review stages, incorporating visual inputs such as airspace charts to enhance situational understanding. Our system, operates in two phases: (1) a multimodal LLM generates flight plans

conditioned on textual mission requirements, and (2) a secondary LLM acts as a self-review agent, evaluating the generated plans for feasibility, safety, and regulatory compliance.

To enable multimodal reasoning, we leverage a VLM that integrates spatial features with domain-specific flight constraints, allowing it to generate route suggestions, waypoint justifications, and alternate plans flight planning scenarios. We validate our approach using simulated flight scenarios sourced from aviation datasets. Quantitative metrics show significant improvements in route optimality, safety constraint satisfaction, and interpretability compared to traditional planning pipelines. Moreover, qualitative results highlight the coach LLM's ability to detect subtle errors, such as misaligned airspace boundaries or infeasible altitudes.

This work demonstrates the promise of a closed-loop LLM framework for safe and efficient autonomous flight planning, and opens new directions for human-AI collaboration in safety-critical domains. We release all models, prompts, and evaluation tools to facilitate future research.

3 - Implicit Learning of Riemannian Polynomials for Quadrotor Trajectory Optimization

Yuwei Wu, University of Pennsylvania, Philadelphia, PA, United States

This talk addresses the problem of generating optimal trajectories on Lie Groups with left-invariant Riemannian metrics, a challenge that traditionally requires solving nonlinear boundary value problems through numerical methods. We develop a coordinate-free framework to learn optimal smooth trajectories using implicit neural networks with an arbitrary initial and final state, including non-homogeneous boundary conditions with any non-rest start and end state. We parameterize the trajectory via higher-order polynomials and construct a loss function that incorporates the necessary conditions for optimality and boundary conditions. The proposed framework is evaluated against numerical optimization methods, and the optimality is analyzed to validate the proposed approach. Furthermore, we demonstrate the capacity of our method to generate piecewise trajectories through multiple waypoints, which can be efficiently integrated into quadrotor trajectory planning and control frameworks.

4 - Real-Time Safe and Energy-Efficient Uav Motion Planning in Windy Urban Environments

Spencer Folk, University of Pennsylvania, Philadelphia, PA, United States

Recent advancements in hardware and software are bringing autonomous aerial vehicles closer than ever to delivering futuristic visions of flying cars and package delivery drones. However, the safe deployment of autonomous aircraft at scale in urban environments poses significant challenges, one of which being uncertainties contributed by complex wind fields. Building clusters generate dangerous high speed wind flow patterns which increase both the costs and risks for aerial operations. Existing solutions rely on either distributed sensors, extensive exploration, or accurate global representations of the environment with expensive offline calculations.

In this talk, we first introduce a novel approach to predicting wind flow fields in real time, without GPS or prior knowledge of the environment, and only using on-board sensing. We accomplish this by strategically reducing the problem by predicting the wind flow field on a local robot-centered domain and thus leveraging the predictability of the wind flow field induced by conservation of mass and momentum constraints from nearby topography. Using vast amounts of simulated winds through procedurally generated urban environments, we train deep neural networks to synthesize navigational LiDAR scans with sparse in-situ measurements of the wind, achieving real-time prediction rates and surprising generalizability. In the latter half of the talk, we demonstrate how the local wind prediction can be incorporated into a receding horizon optimal control architecture to reduce crash rates and energy consumption. The combined system can perceive surrounding winds in real time with on-board sensors and adjust the planned route on the fly.

5 - Enabling Formal Guarantees in Learning-Based Autonomy with Challenging Dynamics

Shreyas Kousik, Georgia Institute of Technology, Atlanta, GA, United States

As robots become more widespread through society, we have an immense opportunity to improve their performance and integration through massively parallelized scaling of data collection and learning, we are already seeing this with autonomous driving. At the same time, this means it is absolutely critical to ensure that such learning-enabled robots are safe, especially in aviation. To this end, this talk presents our recent efforts in learning of and with formal guarantees. The key idea is that safety and performance are not necessarily a tradeoff, as one might initially suspect. Careful design of both learning and deployment can in fact get the best of both worlds.

Prescriptive and Predictive Analytics in Logistics and Supply Chain

Invited Session

The Practice Section of Informs

Chair: Nitish Umang, Johnson & Johnson, Clifton Park, NY, United States

1 - Weekly Home Healthcare Routing and Scheduling with Overlapping Patient Clusters

Ai Zhao, Johnson & Johnson, Plano, TX, United States

We present a two-step approach for efficiently solving a weekly home healthcare scheduling and routing problem. Two new MIP models are proposed, where the first is used for making patient-therapist assignments over the week, and the second for deriving daily routes. In both MIPs, the objective function contains a hierarchically weighted set of goals. The major components of the full problem are continuity of care, downgrading, workload balance, time windows, overtime, and mileage costs. A new preprocessing procedure is developed to limit the service area of each therapist to a single group of overlapping patients. Once the groups are formed, weekly schedules are constructed with the MIPs. The overall objective is to minimize the number of unscheduled visits and total travel and service costs subject to the operational and physical constraints mentioned above. Computational experiments are conducted with real data sets provided by a national home health agency. The results show that optimal solutions can be obtained quickly for large-size instances, and that they compare favorably with results obtained with a proposed integrated model as well as the actual schedules.

2 - AI-Based Smart Inspection and Anomaly Detection in Supply Chain

Reyhaneh Nosrati, Johnson & Johnson, Raritan, NJ, United States, Sandhya Kamineni, Anu Ahuja, Rami Musa, Saman Sarraf

This work presents two machine learning-based solutions designed to automate inspection processes for Johnson & Johnson products, demonstrating how Machine Learning can enhance quality assurance and operational efficiency.

The first, Automated Staple Inspection (ASI), focuses on the Ethicon EndoCutter stapler, a crucial surgical device. Currently, staple quality is assessed manually on small samples, producing binary Pass/Fail results that lack detail. The proposed ML system employs advanced computer vision techniques to perform highly granular inspections, achieving over 99% accuracy in staple form detection, height estimation, and outline measurement—surpassing KPI thresholds of 95%. This enables quantitative inspection, reduces manual reliance, and prevents revenue loss. The solution's stability and scalability, combined with cost benefits, project savings of \$230 million over ten years.

The second solution, AI-based Smart Inspection (AIS), addresses the verification of orthopedic joint reconstruction surgical trays. These trays contain numerous components arranged in designated slots, requiring precise presence and placement checks. Replacing manual inspection, the AI pipeline employs a comprehensive model capable of identifying up to 3,145 classes with over 90% accuracy. Its scalable architecture minimizes maintenance costs while ensuring high inspection fidelity, streamlining quality workflows and reducing operational costs.

Together, these solutions exemplify Johnson & Johnson's leadership in AI-driven automation, delivering high-precision, scalable, and cost-effective inspection methods. These innovations significantly improve product safety, quality, and operational efficiency in medical device manufacturing.

3 - Multi-Product 3D Container Load Planning in Outbound Logistics Operations

Nitish Umang, Johnson & Johnson, Clifton Park, NY, United States

The multi-product three-dimensional container loading problem (3D-CLP) involves packing heterogeneous cases into a three-dimensional space in a space-efficient manner. This problem has broad applications in supply chain and logistics planning across various industries where physical products must be loaded and packed for storage and/or shipment to different destination locations. The importance of 3D-CLP is evident in its applicability across a range of physical loading processes, such as the loading of multiple shipping cases from one or more product categories into a gaylord container or onto a pallet, and the subsequent loading of multiple gaylords or pallets into a transport container, such as an ocean container or a truck trailer.

Generating high-quality loading plans in three-dimensional space within reasonable computation times can be especially challenging in many commonly encountered real-world use cases. We developed a decision-aid tool called LoadMax that leverages optimization-based techniques to address this challenge of balancing solution quality and computational efficiency for outbound operational planning. The tool has been implemented and deployed to create highly efficient loading plans for gaylords and trucks used in daily operations at a major distribution logistics site at Johnson & Johnson, leading to significant operating cost savings, and is currently being expanded to other sites in North America and Europe.

4 - Optimizing the Orthopedic Supply Chain: Machine Learning-Based Forecasting for Implant Sizing and Surgical Demand in Tka and Tha

Ziqing Zhao, Johnson & Johnson, New Brunswick, NJ, United States

Accurate component sizing in TKA and THA procedures is essential for optimizing clinical outcomes to avoid early failures and excessive costs associated with shipping and maintaining additional surgical trays. Existing methods of implant size predictions for TKA and THA procedures, which include templating, are not very reliable and are time consuming. We have developed and produced machine learning algorithms that leverage real-time patient case data via direct customer Electronic Health & Medical Records (EHR/EMR) integration and provide instant case need predictions. In this work, we developed five ML algorithms that were trained using patient biometrics variables such as height, weight, age, gender, body mass, and surgeon preference indices and productionized the models that exhibited the best accuracies for each procedure. Our models achieve high accuracy rates: up to 95% for ATTUNETM Primary Knee System tibial and femoral components, 80% for hip stems, 87% for hip cups, and 98% for patella; and 80% for the EMPHASYS™ Acetabular Solutions cup. Recently, size prediction models for the EMPHASYS™ cup and ATTUNETM patella were successfully deployed on the Johnson & Johnson MedTech Orthopaedics Advance Case Management platform, a proprietary digitally integrated system that simplifies pre-surgery processes by utilizing case schedules and patient data.

Site Capacity Management and Optimization

Invited Session

Practice Track

Chair: Francisco Castillo Zunino, Amazon, Atlanta, GA, N/A, United States

1 - Site Capacity Optimization: Defining Operational Capacity Frontiers

Francisco Castillo Zunino, Amazon, Luxembourg, Luxembourg, Matias Siebert, Filippo Fedeli, Thomas Øvestad, Inaki Estella Aguerri, Dajun Yue

Accurate capacity planning is a critical challenge in large-scale sorting and distribution centers. While traditional approaches often rely on single-dimensional capacity limits, operational reality shows that different package types compete for shared resources in complex ways. We present a novel approach to site capacity optimization that maps the trade-offs between processing different package types. Rather than defining fixed capacity limits, we develop a mathematical framework that generates multi-dimensional capacity frontiers, revealing how increasing the processing of one package type necessarily impacts the capacity for others. The proposed framework provides facility managers with more precise capacity profiles for operational planning while generating convex constraints suitable for network-wide optimization problems.

2 - Comprehensive Capacity Optimization of the Amazon Transportation Network

Marc Christian Bataillou Almagro, Amazon, Paris, France

Modern transportation networks process millions of packages weekly through integrated planning of labor under-the-roof (UTR) and truck scheduling on-the-road (OTR). This paper introduces a mathematical formulation that bridges virtual package flows with physical transportation constraints, addressing a critical gap in capacity optimization. Our approach integrates operational scheduling constraints with network realities, eliminating infeasible flow plans and reducing capacity adjustments by 10%. We contribute solution methodologies tailored to large scale fulfillment networks: (i) an adaptive discretization scheme that manages high dimensional optimization spaces, (ii) constraint propagation techniques that reduce problem size by 92%, (iii) strategic clustering of commodities and paths that decreases variables by 90%, and (iv) equipment type selection heuristics for optimal truck pre assignment. These innovations enable solving billion variable capacitated network design problems in under 10 minutes.

Decision Analysis in Military Environments

Invited Session

Military and Security

Chair: Tyler Perini, U.S. Naval Academy, Washington, DC, United States

1 - Logistics Resilience in Isolated Environments: Insights from Hawai'i

Isabella Sanders, Dept. of Systems Engineering, United States Military Academy, Newburgh, NY, United States

Isolated regions face outsized disruption risk from hazards, labor shocks, and geopolitical events. We present a simple, transferable framework to assess logistics resilience in isolated environments, illustrated with Hawai'i. Using realistic flow and lead-time estimates across retail supply chains, we simulate targeted lane outages and capacity constraints to quantify unmet demand, recovery time, and stockout propagation. We compare resilience levers, redundancy, calibrated buffers, dynamic rerouting/mode shifts, and information sharing finding two consistent patterns: (1) modest flexibility (transshipment, alternate modes) often outperforms equivalent static redundancy for short, moderate shocks; (2) for sustained disruptions, hybrid strategies that pair right-sized buffers with flexible routing minimize downstream shortages without prohibitive holding costs. The framework supports mission-assured sustainment planning for public and private stakeholders and offers a concise playbook for pre-positioning, diversification, with extensions to cross-sector wargaming and contested-logistics exercises.

2 - Resilience Models for Armament Supply Chains

Benjamin Armstrong, Purdue University, West Lafayette, IN, United States

The resilience of the U.S. military's ammunition supply chain is a critical factor in sustaining combat operations during prolonged or high-intensity conflict. Recent global events and the prospect of near-peer competition have revealed potential vulnerabilities in production, distribution, and surge capacity. This research addresses these challenges by first mapping the ammunition supply chain from the sourcing of raw materials through production and assembly to final distribution and delivery. Developing this comprehensive map provides the foundation for constructing reliable models of current supply chain capabilities.

Drawing on industry-derived data, these models simulate potential surge scenarios to assess vulnerabilities, evaluate scalability, and analyze the cost implications of different courses of action. By quantifying both system performance and cost under stress, the models provide decision makers with a clearer understanding of current readiness and the areas most in need of investment. Beyond modeling, the research also explores alternative materials, manufacturing methods, and readiness-enhancing measures that could improve resilience, provide redundancy in supply and distribution, and enhance flexibility during crises.

This integrated approach offers a framework for strengthening supply chain robustness and adaptability. The findings aim to bridge the gap between industry best practices and military requirements, supporting more informed policy, acquisition, and operational decisions. Ultimately, this work contributes to ensuring ammunition supply remains a reliable enabler of readiness, providing the Army with the capacity to meet the demands of future conflicts without disruption.

3 - Impact of Stochastic Travel TIMES on the Military Port Selection Problem

William Titus, Air Force Institute of Technology, Wright-Patterson AFB, OH, United States, Brian Lunday, Jesse Wales

This research analyzes the impact of stochastic inland and oceanic travel times on port selection for large-scale deployment mobilization. A stochastic mixed-integer programming model seeks to minimize the average arrival time of equipment into theaters. In the first stage, it selects ports to open and assigns installations and ships to open ports. In the second stage, it considers realized travel times and routes equipment to ports and onto sealift ships for overseas transit. Testing applies Sample Average Approximation to a realistic scenario for deployments from the United States to two overseas theaters. Over instances manifesting a range of parametric value combinations, results indicate a critical point of diminishing marginal returns for opening additional ports, as well as relative solution quality for alternative assumptions about the correlation of travel times' stochasticity. Uncorrelated stochasticity reduces port congestion and enables a 2.3% faster average arrival time. For different port opening limitations, subsequent analysis identifies up to a 90% degree of solution similarity, indicating robustness for selected port opening decisions. Testing also identifies that correct assumptions about parametric stochasticity reduce average arrival times by up to 1.2%, indicating the value of validating such information for mobilization planning.

4 - Bayesian Graph Traversal

William Caballero, Air Force Institute of Technology, Wright-Patterson AFB, OH, United States, Phil Jenkins, David Banks, Matthew Robbins

This research considers Bayesian decision-analytic approaches toward the traversal of an uncertain graph. Namely, a traveler progresses over a graph in which rewards are gained upon a node's first visit and costs are incurred for every edge traversal. The traveler knows the graph's adjacency matrix and his starting position, but does not know the rewards and costs. The traveler is a Bayesian who encodes his beliefs about these values using a Gaussian process prior and who seeks to maximize his expected utility over these beliefs. Adopting a decision-analytic perspective, we develop sequential decision-making solution strategies for this coupled information-collection and network-routing problem. We show that the problem is NP-Hard, and derive properties of the optimal walk. These properties provide heuristics for the traveler's problem that balance exploration and exploitation. We provide a practical case study focused on unmanned aerial systems in security operations and empirically study policy performance in myriad Erdos–Renyi settings.

5 - Artificial Intelligence-Enabled Red Team Evaluation of Deep Learning-Powered Military Information Systems

Dinesh Sharma, University of South Florida, Tampa, FL, United States, Ahtesham Bakht, Ankit Shah, Nathaniel Bastian

Military information systems (MIS) collect, process, and analyze critical data to support defense operations and strategic decisions. By integrating complex imagery from spaceborne and airborne hyperspectral sensors, command-and-control (C2) systems for intelligence, surveillance, and reconnaissance (ISR) enhance situational awareness and enable real-time decision-making. While deep learning (DL) boosts the analytical power of MIS, it also exposes them to adversarial machine learning (AML) threats. Understanding these vulnerabilities is essential to advancing the security and robustness of DL-powered MIS. Stealthy poisoning attacks targeting complex imagery remain largely understudied, underscoring the need for robust red teaming frameworks. To address this gap, we introduce the Deep Stealth Poison Generator (DSPG), a novel framework that combines mathematical optimization, deep reinforcement learning, and encoder-decoder architectures to craft highly stealthy and effective poisoning attacks. Experiments with real-world hyperspectral data reveal critical vulnerabilities in DL-powered MIS, with DSPG achieving greater imperceptibility, stronger resistance to data sanitization, and higher targeted misclassification success rates than existing methods. These findings advance the AML literature by deepening our understanding of poisoning threats against DL-powered MIS reliant on complex imagery, and they inform future efforts to improve their robustness and resilience.

1 - Distributionally Robust Bayesian Control via Optimal Transport: Merton's Problem Revisited

Jose Blanchet, Stanford University, Stanford, CA, United States, Jiayi Cheng, Hao Liu, Yang Liu

Distributionally robust dynamic control often preserves the dynamic programming principle (DPP) for tractability, but this can induce conservatism. We place an optimal transport (OT) ambiguity set on a Bayesian prior for key parameters, relaxing DPP while yielding less pessimistic policies. Our case study is Merton's portfolio selection with medium-horizon objectives (months) in which drift is difficult to estimate, possibly time-varying and unpredictable on these horizons. Volatility, on the other hand, can be screened from higher frequency estimates (hours–days) or implied market estimates. While the screening can affect asset classes, the environment provides a reasonable framework to test the impact of introducing model robustness in a targeted approach. To implement this approach, we develop three results: (i) a min–max duality that collapses the robust control game (without DPP) to a static distributional optimization over priors; (ii) a sensitivity analysis in the ambiguity radius for the resulting nonlinear program, enabling efficient approximations; and (iii) a nonlinear OT projection that calibrates the ambiguity radius from data, generalizing linear projection schemes from statistical distributionally robust optimization (DRO). We evaluate the framework on synthetic and real-market datasets, benchmarking against static DRO and traditional robust control. The experiments clarify when distributionally robust Bayesian control outperforms, and how the gains vary with horizon and volatility screening.

2 - On the (Im)possibility of Beating "Plug-In" Optimization

Henry Lam, Columbia University, New York, NY, United States, Garud Iyengar, Tianyu Wang

Many modern decision-making pipelines entail optimization problems driven by data and the need to mitigate uncertainty. This has ignited a range of proposed approaches in recent years, including various (distributionally) robust optimization and regularized formulations. We explore the fundamental question of when optimization based on simple "plug-in" estimates of unknown quantities is superior among these approaches. Our comparison uses suitable notions of stochastic dominance on the optimality gap or regret, and is based on an uncertainty symmetry concept that holds regardless of whether the uncertainty comes from statistical noise, unpredictable shifts, or both. Finally, we discuss the converse question of when we can improve upon "plug-in" optimizers.

3 - Properties of Turnpike Functions for Discounted Finite Mdp's

Eugene Feinberg, Stony Brook University, Stony Brook, NY, United States, Gaojin He

This paper studies discounted Markov Decision Processes (MDPs) with finite sets of states and actions. Value iteration is one of the major methods for finding optimal policies. For each discount factor, starting from a finite number of iterations, which is called the turnpike integer, value iteration algorithms always generate decision rules which are deterministic optimal policies for the infinite-horizon problems. This fact justifies the rolling horizon approach for computing infinite-horizon optimal policies by conducting a finite number of value iterations. This paper describes properties of turnpike integers and provides their upper bounds.

4 - An Invariance Principle for the Thinned Power of Choice Algorithm

Rami Atar, Technion, Haifa, Israel, Gershon Wolansky

For a thinned version of the power-of-choice, we study an asymptotic regime where the number of servers grows while each queue is kept in "conventional" heavy traffic (i.e., each queue length fluctuates diffusively). Assuming a finite second moment of otherwise general service times we establish an invariance principle, with the diffusion limit given by a McKean-Vlasov SDE.

5 - On a General Optimal Control-Based Approach for Reinforcement Learning

Mark Squillante, Mathematical Sciences Department, IBM Research, Yorktown Heights, NY, United States, Weiqin Chen, Chai Wah Wu, Santiago Paternain

We devise a control-based reinforcement learning approach to support direct learning of the optimal policy, establishing its theoretical convergence, optimality and gradient properties. Numerical results demonstrate significant improvements in quality, complexity, and runtime.

Optimizing Passenger and Freight Rail with Energy and Automation Perspectives.

Invited Session

Railway Applications

Chair: Xuesong Zhou, ITE ASU, Tempe, AZ, United States

1 - Beyond the Horizon: Valuing Flexibility in Urban Rail Extension Decisions Under Political Cycles and Present Bias

Qianwen (Vivian) Guo, Florida State University, Tallahassee, FL, United States, Ziyue Li

This paper formulates and solves the extension problem for urban rail transit lines within a real options framework. Motivated by empirical observations of political cycles inducing quasi-hyperbolic discounting, we incorporate time-inconsistent preferences, specifically present bias, of decision-makers, which violates standard exponential time preference. We employ a quasi-hyperbolic discount function to model preferences within a compound real option valuation framework. The multi-dimensional decision problem involves determining the optimal exercise policy for the compound option, including timing, scale (capacity), and discrete route selection under stochastic project value dynamics. We analyze the strategic implications of time-inconsistency by considering equilibrium concepts for naive and sophisticated agents within an intra-personal game framework. The model derives the optimal exercise boundaries (trigger values) for the investment option. Sensitivity analyses are conducted to quantify the impact of key system parameters and uncertainty levels on the optimal investment policy and resulting project characteristics. This study provides rigorous insights into how time-inconsistency and agent sophistication fundamentally alter optimal infrastructure investment strategies and the value of embedded managerial flexibility.

2 - Intermodal Freight Optimization Through Integrated Railway, Waterway, and Highway Network Modeling

Xuesong Zhou, ASU, Tempe, AZ, AZ, United States

This work enhances intermodal freight logistics by integrating railway, waterway, and highway networks with a focus on operational coordination, disruption resilience, and scalable optimization. Building on POLARIS's regional freight simulation capabilities, we introduce planning and optimization models for intermodal routing, scheduling, and yard operations. Using GMNS+ tools, we construct a multi-resolution freight network that optimizes train blocking plans, block-to-train assignments, and end-to-end shipment flows while accounting for link capacities, yard limits, and transfer times. Our blocking-plan-based traffic assignment enables time-dependent flow simulation and delay resilience analysis under real-world disruptions such as port congestion and demand variability.

3 - Implementation and Analysis of Long-Haul Rail and Intermodal Operations Using Polaris Transportation Framework

Hyunseop Uhm, Argonne National Laboratory, Lemont, IL, United States, Yantao Huang, Abdelrahman Ismael, Olcay Sahin, Hui Shen, Natalia Zuniga, Joshua Auld

The long-haul freight transportation sector faces significant challenges, including a persistent shortage of truck drivers, increasing urban traffic congestion, and instability in the energy supply chain. These factors contribute to significant uncertainty and volatility in shipment costs, particularly for truck-dependent logistics. To address these issues reducing operational reliance on truck-centric operations is a critical strategy for minimizing total transportation costs, improving logistics network stability, and reducing energy consumption.

In this study, POLARIS, an advanced agent-based transportation modeling framework, is used to simulate and analyze intermodal operations. POLARIS is used to generate business-to-business freight shipments, model freight mode and shipment size choices by each commodity flow, simulate freight truck routing and operations, and conduct large-scale transportation simulations across the national long-haul freight network. An optimization model was proposed to minimize total transportation costs by strategically integrating multiple transportation modes (e.g., rail, truck) in intermodal operations.

To support detailed intermodal assessments, the model incorporates train construction and deconstruction, rail schedules, and rail network congestion, enabling more accurate estimations of shipping cost and transit time. The LA-Chicago corridor is used as a case study, pulling from national highway and railway networks. All trucks, railway trains, and shipment containers were dynamically simulated within the POLARIS network.

Finally, the impact on the traffic network and operational delays from this freight redistribution were analyzed under scenarios involving a shift in freight volume from trucks to the railway network.

4 - Train Rescheduling with Considering the Breakdown of the Power Supply System in Metro

Shuai Su, Beijing Jiaotong University, Beijing, China, People's Republic of, Ruihao Zhang

We present a train rescheduling framework for metro systems that accounts for power supply system breakdowns. The methodology optimizes train operations during power failures while minimizing passenger delays and maintaining service continuity. The approach demonstrates improved system recovery and reduced service disruptions.

Re-Inventing Labor Planning at Amazon

Invited Session

Transportation Science and Logistics (TSL)

Chair: Martin Savelsbergh, Amazon Australia, Darlington, WA 6153, Australia

1 - Associate Capacity Forecasting

Selin Tosun, Amazon, Seattle, WA, United States, Jeronimo Callejas

The accurate knowledge on how many Voluntary Extra Time and Ready (on-demand) hours our associate pool has the appetite for in given week becomes crucial in optimal planning and resource allocation, eventually effects the volume processing and efficiency. Hence, many workforce planning modules such as hiring, splitting and planning extra shifts, when and how much head count to account & post, and when & how much to surge is crucial for the operational efficiency. Forecasting the true associate appetite for Voluntary extra time opportunities and Ready opportunities have been challenging, as the historic values has been capped at the head count openings

an extra shift posted with. In other words, the historic data is censored. Similar problems has been seen on retail space, where the real customer appetite trends is unknown when the items go out of stock at certain times. Here in EPS, we study, model, and develop forecasting systems that attacks the censorship in the data by incorporating the censorship within our objective function. We also incorporate the location based embedding coming from census and related datasets. We leverage Fourier Transformations to capture seasonality. We have observed up to 11% improvement with under estimation WMAPE and up to 23% improvement with over estimation WMAPE in the forecasted weekly VET hours, and up to 30% improvement with the under estimation WMAPE and up to 9% improvement with the over estimation WMAPE in the forecasted weekly Ready hours.

2 - Optimizing Capacity: Workforce Regionalization

Hadi Panahi, Amazon, Bellevue, WA, United States, Jeronimo Callejas, Rachel Rutkowski

At the end of Amazon's supply chain, Amazon Logistics (AMZL) delivery stations (DS) must accommodate dynamic customer demand and variations in labor supply reliability, leading to over and under-staffing risk. To minimize this risk, individual DS leverage costly labor planning levers such as Voluntary Extra Time (VET) and surge (i.e., additional compensation). As a cost-effective alternative, we utilized a multi-phased, mixed methods approach to develop and demonstrate the efficacy of a science-based regional labor planning program, referred to as Nodal, which redistributes available labor based on need across nearby stations. We found that Nodal improved labor pool efficiency metrics such as an increase in activity rate of 498 bps (i.e., accepted headcount/eligible headcount), an increase in average hours worked by 430 bps, a decrease in VET utilization by 262 bps, and a decrease in Voluntary Time Off (VTO) utilization by 84 bps. All of these improvements occurred without adversely impacting baseline operational metrics (e.g., attrition, productivity, safety) nor associate or operator satisfaction. These findings suggest that, with guardrails, Nodal can be used to accommodate dynamic customer demand and variation in supply reliability by optimizing the existing AMZL labor pool.

3 - Optimizing Labor use and Availability on the Day of Operations

Nayeon Kim, Amazon, New York, NY, United States, Ramon Auad, Zeynep Sargut

Amazon's commitment to fast delivery options, including same-day service, creates significant demand volatility at facilities until the day of operations. This volatility particularly affects last-mile facilities like Delivery Stations (DS) and Sub-Same Day stations (SSD), requiring agile workforce management to maintain reliable service and lean operations. To address this challenge, Amazon's intra-day planning system dynamically adjusts under-the-roof (UTR) labor plans from the day before operations through the day of operations. The system identifies gaps between existing capacity from current work plans and capacity needs based on updated forecast. It leverages Voluntary Extra Time (VET) and Ready labor to address understaffing and Voluntary Time Off (VTO) to minimize labor costs during periods with overstaffing. The system also optimizes workforce assignment across different processes throughout the day to maximize labor utilization and total throughput. In this presentation, we outline the system architecture and its supporting modules that collectively enable flexible labor planning while maintaining operational reliability and cost efficiency. Each module addresses a specific challenge as a generic solution, such as optimal VTO planning. This modular approach achieves better scalability and explainability while allowing adaptation to different planning horizons and business contexts, ensuring broad applicability across Amazon operations.

4 - Conceptualizing Labor Planning as a Dynamic Process: Developing a Versatile Qualitative Dataset to Support Large Language Models

Alana Scholl, Amazon, New York, NY, United States

Labor planning for Under-The-Roof (UTR) operations is a complex process characterized by numerous inputs, reliance on multiple roles for feedback and approval, site-specific nuances, time-sensitivity, and adverse outcomes for the business, operators, and associates should labor plans fail to reflect reality. In an effort to optimize the time and effort of labor planners, there have been efforts to develop real-time support resources, such as large language model chatbots, to automate and expedite aspects of the labor planning process. However, to do this effectively, we must have a comprehensive understanding of *what* planners do, how they execute their tasks, and how they make decisions while navigating disparate tradeoffs. Existing standard operating procedures (SOPs) do not capture this level of detail. As such, we leveraged a modified hierarchical task analysis (HTA) approach using three forms of data collection including 1) artifact analysis of existing SOPs and subject matter expert interviews, 2) structured observations and modified contextual-inquiry based observations the labor planning process, and 3) modified critical incident technique interviews with planners. Using this approach, we were able to effectively and efficiently capture the labor planning process as a series of contextualized, interdependent decision points with an HTA structure and process map as initial outputs. From there, we were able to reformat the data to support multiple use cases including: LLM fine-tuning, updating onboarding materials, and developing SOPs to establish and monitor quality standards.

5 - Large Language Models for Model Explainability: a use-Case in Labor Planning

Anis Ben Said, Amazon, Seattle, WA, United States, Roman Levkin, Thomas Fillebeen, David Dong, Brian Salisbury

Amazon's Under-The-Roof (UTR) operations—comprising fulfillment centers, sort centers, and delivery stations—employ hundreds of thousands of associates and require sophisticated labor planning. Current labor planning models provide complex planning decisions by balancing demand fulfillment and labor cost minimization, while accounting for numerous operational constraints, influencing hiring and scheduling decisions for hundreds thousands associates. However, these models often act as “black boxes” for the planners who use them, who do not have specialized optimization knowledge. As a result, planners spend large amount of time investigating model recommendations and tweaking model inputs to derive their desired results, potentially leading to reduced trust and suboptimal manual adjustments.<div c-

Recent advancements in Large Language Models (LLMs) have demonstrated capabilities in explaining complex systems such as code bases and mathematical models. This research introduces a generalizable framework for model explainability through LLM agents and applies it to the labor planning space. The framework presents a modular architecture design alongside implementation methods that enable rapid development of GenAI based chatbots specialized in explaining diverse model types. While our initial focus has been on optimization models for labor planning, the approach can be adapted to any model requiring human interpretation. Using this framework, we have successfully onboarded multiple labor planning models, demonstrating significant improvements in planner efficiency and decision quality.

1 - Optimizing LLM Inference: Fluid-Guided Online Scheduling with Memory Constraints

Ruicheng Ao, MIT, Cambridge, MA, United States

Large Language Models (LLMs) are indispensable in today's applications, but their inference procedure requires substantial computational resources, especially when memory is limited. This paper treats LLM inference optimization as a multi-stage online scheduling problem, where prompts arrive sequentially and the incremental expansion of the Key-Value (KV) cache during inference renders conventional scheduling algorithms ineffective. To address this challenge, we develop a fluid dynamics approximation to establish a tractable benchmark, providing insights for devising effective scheduling algorithms. We introduce the Waiting for Accumulated Inference Threshold (WAIT) algorithm for known output lengths and extend it to the Nested WAIT algorithm for unknown output lengths. Both algorithms achieve near-optimal performance compared with the fluid benchmark under heavy traffic limits, balancing throughput, latency, and Time to First Token (TTFT). Numerical experiments with Llama-7B on an A100 GPU demonstrate superior throughput and reduced latency compared to widely adopted baselines.

2 - Efficient Gradient Estimation for Overparameterized Stochastic Differential Equations

Shengbo Wang, University of Southern California, Los Angeles, CA, United States

Overparameterized stochastic differential equation (SDE) models have achieved remarkable success in various complex environments, such as PDE-constrained optimization, stochastic control and reinforcement learning, financial engineering, neural SDEs, and generative AI. These models often feature system evolution coefficients that are parameterized by a high-dimensional vector θ in $\mathbb{R}^n$, aiming to optimize expectations of the SDE, such as a value function, through stochastic gradient ascent. Consequently, designing efficient gradient estimators for which the computational complexity scales well with n is of significant interest. We introduce an unbiased stochastic gradient estimator—the generator gradient estimator—for which the computation time remains stable in n . In addition to establishing the validity of our

methodology for general SDEs with jumps, we also perform numerical experiments testing our estimator in a linear quadratic control problem where the policy is parameterized by high-dimensional neural networks. The results show a significant improvement in efficiency compared to previous methods: our estimator achieves near-constant computation times, increasingly outperforms its counterparts as n increases. These empirical findings highlight the potential of our proposed methodology for optimizing SDEs in contemporary applications.

3 - Vc Theory for Inventory Policies

Yaqi Xie, University of Chicago, Chicago, IL, United States

There has been growing interest in applying reinforcement learning to inventory management, alongside a recent stream of work advocating for supervised learning approaches that directly optimize inventory decisions using full historical demand trajectories. While empirically promising, there has been no theoretical understanding of supervised learning in inventory management problems, where inventory is dynamically replenished over time. This paper provides the first generalization guarantees for supervised learning of several well-known classes of dynamic inventory policies, including base-stock and (s, S) policies, using tools from the celebrated Vapnik-Chervonenkis (VC) theory, such as the Pseudo-dimension and Fat-shattering dimension. Our results have implications for regret against the best-in-class policies, and allow for an arbitrary distribution over demand sequences, which makes no assumptions such as independence across time. Surprisingly, we prove that the class of policies defined by TS non-stationary base-stock levels exhibits a generalization error that does not grow with TS , whereas the two-parameter (s, S) policy class has a generalization error growing logarithmically with TS . Overall, our analysis leverages specific inventory structures within the learning theory framework, and improves sample complexity guarantees even compared to existing results assuming independent demands.

4 - Distributed Load Balancing with Workload Dependent Service Rates

Wenxin Zhang, Columbia University, New York, NY, United States

We study distributed load balancing in bipartite queueing systems where frontends route jobs to heterogeneous backends with workload-dependent service rates. The system's connectivity -- governed by compatibility constraints such as data residency or resource requirements -- is represented by an arbitrary bipartite graph. Each frontend operates independently without communication with other frontends, and the goal is to minimize the expected average latency of all jobs. We propose a closed-loop policy called the Greatest Marginal Service Rate (GMSR) policy that achieves effective coordination without requiring knowledge of arrival rates. In a discrete-time stochastic model, we show that the behavior of our routing policy converges (almost surely) to the behavior of a fluid model, in the limit as job sizes tend to zero and job arrival rates are scaled so that the expected total volume of jobs arriving per unit time remains fixed. Then, in the fluid regime, we demonstrate that the policy attains an ϵ -suboptimal solution in $O(\delta + \log 1/\epsilon)$ time from δ -suboptimal initial workloads, which implies global convergence to the centrally coordinated optimal routing. Finally, we analyze the fluid model when the system is overloaded. We show that GMSR lexicographically maximizes throughput, maximizes the number of stable backends, and minimizes their collective workload.

Mitigating the Impacts of Wildfires on Electric Power Systems through Stochastic Optimization

Tutorial session

Tutorials

Chair: Brian Denton, University of Michigan, Ann Arbor, MI, United States

1 - Mitigating the Impacts of Wildfires on Electric Power Systems Through Stochastic Optimization

Chaoyue Zhao, University of Washington, Seattle, WA, United States, Ruiwei Jiang, Juan-Alberto Estrada-Garcia, Xinyi Zhao, Alexandre Moreira

Dry and windy weather conditions significantly increase the risk of wildfires, whose spread exacerbates the vulnerability of the grid and results in prolonged power outages. This tutorial introduces and reviews recent streams of studies on addressing this challenge through stochastic optimization approaches, including static, adaptive, dynamic, and distributionally robust models. In particular, we account for random failures of power lines, which depend not only on the ambient environment (such as temperature, wind speed, and fire) but also on the power flowing through the line, introducing decision-dependent uncertainty (DDU). We introduce the modeling of wildfire, power systems operations, and their interactions, as well as how stochastic optimization models can characterize DDU and mitigate the impacts of wildfires on electric power systems. As examples, we mention three models, ranging from long-term planning to short-term and dynamic reconfiguration of a power system amidst wildfire-prone conditions. For each model, we provide a numerical case study to demonstrate the value of modeling (e.g., DDU and dynamic reconfiguration) in mitigating the impacts of wildfires.

Uncertainty in Resource Allocation

Invited Session

TSL: Freight Transportation

Chair: Christine Nguyen, Northern Illinois University, Dekalb, IL, United States

1 - Technician Routing/Scheduling and Parts Management with Demand Uncertainty**Stephanie Santiago-Montano, Auburn University, Auburn, AL, United States, Daniel Silva, Alice Smith**

The technician routing and scheduling problem is encountered in several industries where equipment installation/maintenance at different locations is required. As factors such as demand uncertainty, time windows, skilled staff requirements, and multiple visits come into play, the problem complexity increases. Moreover, for home service companies (HVAC, plumbing, electrical, etc.) to maintain a competitive advantage, they need efficient management of their limited resources. Technological advances like drones can help make this part of the supply chain more cost-effective, faster, and eco-friendly. The combination of traditional trucks and drones can provide an efficient system in which vehicles complement each other to overcome the challenges/disadvantages that each one has. The efficiency of home service networks greatly depends on proper inventory management and efficient technician routing/scheduling. Most studies focus on these problems individually. Considering both simultaneously could result in cost savings and an overall network efficiency increase. This work studies an integrated routing/scheduling and inventory management problem with stochastic demands using a truck/drone tandem. In this problem, demands for spare parts are revealed throughout the day (i.e., demands are placed during a technician visit to the customer location, when the technician diagnoses the needs) and are unknown before the request time. To solve this problem, a rolling-horizon algorithm that seeks the best possible myopic policy is developed. Instances are generated to compare the performance of traditional truck-based networks and the proposed tandem network. Furthermore, this approach is compared to an alternative that waits until multiple demands are revealed. Managerial insights are then provided.

2 - Network Restoration Problem with Heterogeneous Crews Under Incomplete Information**Youssef Nsouli, Rensselaer Polytechnic Institute, Troy, NY, United States, Bahar Cavdar**

We consider a disrupted infrastructure network in the aftermath of a disaster where the planners know the locations of the service outages, but have incomplete information on the actual damage locations. The planner's goal is to determine the routes for two heterogeneous repair crews, a high-skill and a low-skill crew, where the low-skill crew can only repair a subset of damages, to minimize the total service disruption duration experienced by all customers. We formulate this problem as a Markov decision process. We first analyze the structural properties of optimal policies; we consider the one-crew (high-skill) only variant of the same problem and explore how to integrate the low-skill crew without impeding the high-skill crew. We then develop a solution method based value approximation using reinforcement learning, integrating our structural results.

3 - Data-Driven Bunker Refueling Under Price Uncertainty**Qinghe Sun, The Hong Kong Polytechnic University, Hong Kong, Hong Kong**

Bunker refueling decisions in international shipping are crucial operational choices. Each ship acts like a movable storage unit navigating through diverse markets, procuring bunker fuels from different ports to sustain its voyage. This involves grappling with challenges posed by varying bunker fuel prices over time and locations. To address this, we propose data-driven structure-prescriptive (SP) approaches that combine the strengths of modern machine learning with the insights from traditional OR modeling and optimization. Instead of predicting future fuel prices, our approach directly learns the optimal policy from data and adapts refueling decisions to the current market conditions, including fuel prices, crude oil price, NYSE index, etc. Our focus lies in leveraging the well-established understanding that the optimal refueling decision adheres to a state-dependent base-stock refueling policy. This decision depends on factors such as the port of call, fuel tank capacity, market conditions, and is finite-valued, depending on the ship's schedule and voyage. We provide a practical framework to incorporate these structural properties into data-driven decision-making. The finite-valued property, for instance, establishes a connection between the refueling problem and multiclass classification, integrating OR modeling with machine learning. We test our approach through experiments under both simulated scenarios and a real-world example involving the Asia-North America Trade Route. The proposed SP approaches successfully recovered the "true" optimal refueling policy in synthetic simulations. Our real-world data experiments further demonstrate that integrating structural properties into the learning process enhances the quality of prescriptions, particularly when training data is limited.

4 - How to use the Concept of Fragility to Guide the Design of Robust Timetables**Marcella Samà, Roma Tre University, Rome, Italy, Marta Leonina Tessitore, Giorgio Sartor, Carlo Mannino, Dario Pacciarelli**

A robust timetable is crucial for any efficient rail transport system. A typical way to increase the robustness of a timetable is to include buffer times, which can be used to mitigate delays. Other approaches, instead, improve the timetable robustness by considering the possibility of mitigating delays in real-time through dispatching. In this work, we propose a Mixed Integer Linear Programming model to build robust timetables by focusing on their most vulnerable components. This model comprises a set of timetable variables and associated constraints, and a collection of dispatching sub-models related to the fragility of the considered scenarios. We apply our methodology to a real-world case study involving a Norwegian railway line to demonstrate the significant benefits of applying a fragility-based approach to timetable design. We start by computing the fragility of a timetable, for each train-resource pair, by solving a dispatching problem for each delay scenario. Focusing on the most fragile train-resource pair, we apply a delayed row generation scheme in order to dynamically generate most timetabling and dispatching conflict avoiding constraints in the model. We then integrate the proposed algorithm into an iterative process, where the timetable is repeatedly optimized to reduce the fragility of the most fragile train-resource pair. By doing this, we are able to reduce the fragility of the most critical pair, in each iteration, even when keeping the new timetable as close as possible to the original one.

5 - Stochastic Supply Chain Network Design for Fair Resource Allocation**Christine Nguyen, Northern Illinois University, Dekalb, IL, United States, Gabriela Ibarra, Mike Hewitt**

Acting as a vital link between food-insecure individuals and locally sourced food donors, not-for-profit food distributors provide millions of meals to individuals in need. Not-for-profit food distribution networks typically consist of two key members: donors and food banks. Donors provide physical goods and food banks allocate the donations. Effective collaboration between donors and food banks plays a vital role in reducing food waste, and addressing a major concern for these networks – the fair allocation of food. Additionally, the uncertainty of supplier donations and the broad range of variability of demand over time can significantly impact the efficiency of the network. By incorporating the probability of these uncertainties, a network that is more adaptable and responsive to fluctuations in supply and demand can be developed. A two-stage stochastic program is proposed to design a not-for-profit food distribution supply chain network that integrates demand and supply uncertainty, ensures customer satisfaction through service levels, and provides fair allocation. To better serve customers, it is important to consider several strategic and operational questions related to the food distribution network. Research questions in the first stage include: (i) how many consolidation centers should be established and where should they be located? (ii) how many vehicles should be owned? In the second stage: (i) how would external transportation services – such as third-party logistics– supplement the delivery routes from owned vehicles? Disaster relief efforts, blood supply management, and organ transplant operations can greatly benefit from the proposed research.

1 - Spin the Bottle Bill: Deposit-Refund System Policy and Reverse Supply Chain Designs**Austin Saragih, Massachusetts Institute of Technology, Cambridge, MA, United States**

The Bottle Bill, a deposit-refund system policy, charges consumers a deposit upon beverage purchase and refunds it upon return of the empty container to a recycling center. In California and nine other states, the redemption value has remained stagnant at 5 cents for decades, the number of recycling centers has decreased, and recycling

rates have been declining. To address these issues, we spin the Bottle Bill by jointly optimizing its policy and reverse supply chain as a bilevel mixed-integer nonlinear program. At the policy design level, we optimize the redemption value, manufacturers' fees, and distance policy between consumers and recycling centers. Given this distance policy, at the network design level, we then optimize the number of recycling centers for each county in the state. To solve the bilevel problem, we devise a novel solution approach using continuous approximation and monotonicity analysis with optimality and convergence guarantees. Applying our approach to California's Bottle Bill, we provide policy options and insights that the state could implement to achieve its 80% recycling goal, by explicitly and jointly balancing its redemption value and the number of recycling centers. These options and insights can also be adapted to other U.S. states and countries to advance the circular economy of containers.

2 - Effects of Geopolitical Strain on Global Pharmaceutical Supply Chain Design and Drug Shortages

Martha L. Sabogal De La Pava, Clemson University, Clemson, SC, United States, Emily Tucker

Emerging geopolitical risks have begun to threaten global supply chains, including those that produce life-saving drugs. Export bans may prevent a company from shipping products internationally, and it is unclear how these new dynamics may affect company plans and persistent, worldwide drug shortages. To address these questions, we present a global pharmaceutical supply chain design model that considers the risk of export bans that are induced by supplier capacity disruptions and corresponding price increases. The model takes the company's perspective as a decision-maker looking to locate plants and distribute drugs globally. It is a two-stage stochastic program that includes uncertainty in capacity, ability-to-export, and demand. The model is solved by integrating the Sample Average Approximation and L-shaped methods. We present conditions related to when demand will be met and a case study of a generic oncology drug. We find that preparing for geopolitical strain may increase resilience and profits as well as reduce shortages in the short term. At baseline, expected global shortages are high (17.2%) with disparities across country income levels (0.3%, 0.8%, 87.2%, and 87.6% for high, upper-middle, lower-middle, and low income countries, respectively). Pricing policies may improve drug access overall, back-shoring may slightly improve access for the country where it is implemented, and bilateral alliances may not be effective at improving access.

3 - When Where Watt: Harnessing the Value of Time and Location for Renewable Electricity Generation

Vishrut Rana, The Wharton School, Philadelphia, PA, United States, Christian Kaps, Serguei Netessine

Global investment in renewable energy has surpassed \$2 trillion, propelled by cheaper technologies, supportive policies, and energy security needs. Yet profits from renewable generation remain modest, well below the returns from fossil fuel plants, because renewable electricity from wind and solar is often generated at times and in places with low wholesale prices. These lower returns are a central barrier to scaling renewables in line with global climate goals. To enhance profitability of renewable projects, we introduce *Quality Adjusted Power Value (QAPV)*, a siting metric that incorporates the time and location of generation and local prices into investment decisions. Using geospatial satellite data and electricity prices from Texas, we find that 59 wind plants built between 2008 and 2014 would earn median 21% higher annual revenue if sited using QAPV. These gains persist even after accounting for political and infrastructure constraints. We also estimate that marginal wind generation lowers local market prices by 3.8%, translating to consumer benefits of \$1.53 million per site-year under QAPV siting. QAPV thus enables developers to prioritize higher-revenue sites for investment and helps policymakers design support schemes that reward quality rather than just quantity of renewable generation.

4 - Identifying Regions Vulnerable to Obstetric Unit Closures Using Facility Location Modeling with Patient Behavior

Meghan Meredith, NYU Langone Health, Atlanta, GA, United States

The United States has the highest maternal mortality rate among high-income countries. This is just the tip of the iceberg, with many more women experiencing severe complications due to their pregnancy. One commonly cited challenge in maternal healthcare delivery is that many pregnant people lack access to obstetric care, and this has been exacerbated by widespread closures of obstetric units. In this talk, we present a framework for identifying regions that are vulnerable to obstetric unit closures using facility location modeling. When considering the impacts of closures, we incorporate patient care-seeking behavior as many pregnant people "bypass" their closest obstetric facility to deliver at a farther facility. Altogether, we consider a problem in which an adversary seeks to maximize a population's average distance traveled to obstetric care by closing obstetric units. After the adversary closes obstetric units, patients probabilistically select the facility that maximizes their utility under a random utility maximization framework. We demonstrate that this model can be represented as a mixed-integer nonlinear program. Unlike existing facility location models that incorporate consumer choice, our model's objective function is not concave in general and thus, the state-of-the-art algorithms for solving facility location models with choice are not applicable. We introduce reformulations of our problem that lend themselves to solution methods that can take advantage of their decomposable structure. We compare our solution methods in numerical experiments and illustrate our framework using a case study of obstetric care in the state of Georgia.

1 - Game-Theoretic Relaxations in Bilevel Optimization

Noah Weninger, University of Waterloo, Waterloo, ON, Canada, Ricardo Fukasawa

We introduce a framework for relaxing Stackelberg zero-sum games with perfect information, with a focus on those arising from discrete bilevel optimization. The framework consists of operators which transform games while maintaining an approximation or bound on the optimal objective value. This simplifies and generalizes our two previous works on knapsack and matroid interdiction. It also generalizes well-known techniques including the high point relaxation and the derivation of bounds by restricting/relaxing the lower level problem. To further motivate this approach, we apply it to matching interdiction, in which the objective is to interdict (i.e., remove) edges from a graph so that the maximum matching weight is minimized, subject to a knapsack constraint on the set of interdicted edges. We present a branch-and-bound algorithm for this problem which uses a new lower bound derived using our framework.

2 - Solving Integer Robust Optimization Problems with Integer Decision-Dependent Uncertainty Sets

Leonardo Lozano, University of Cincinnati, Cincinnati, OH, United States, Juan Borrero

We study a class of decision-making problems under uncertainty, where the planner hedges against the worst-case realization in an integer uncertainty set that has a functional dependence on the decisions of the planner. We propose three methods to reformulate and solve these problems: the first is based on a single-level 'semi-infinite' reformulation, where the dependence of the uncertainty on the decisions is modeled with auxiliary binary variables; the second is based on a single-follower bilevel reformulation; and the third one is a multiple-follower bilevel reformulation where each robust constraint is associated with a follower. We provide additional enhancements to strengthen the linear programming relaxation of the single-level formulation and propose a column and constraint generation algorithm to solve it. The multiple-follower bilevel formulation is further transformed into a multicommodity flow single-level mixed-integer problem by exploiting recent advancements in decision diagrams. We perform numerical experiments that show the column and constraint generation algorithm can solve small- and medium- scale instances within a few minutes. This method is outperformed by the multicommodity flow formulation when dealing with problems with a single robust constraint. We complement our experiments by using the column and constraint generation algorithm to solve a constrained shortest path problem with maintenance decisions and uncertain arc failures. The proposed method can solve instances of this problem with hundreds of nodes and thousand of arcs in a few minutes.

3 - A Bilevel Optimization Approach for A Class of Combinatorial Problems with Correlated Disruptions and Probing

Jaime Y. Perez, University of South Florida, Tampa, FL, United States, Juan Borrero

We study linear combinatorial optimization problems in which uncertain disruptions can affect the objective function coefficients. A decision maker, or planner, can allocate a limited probing budget to fully reveal the disruption status of selected components. Then, in a second stage, the planner solves the combinatorial problem and executes a solution plan based on the partial information discovered by probing and estimating the remaining uncertainty. In contrast to traditional settings assuming independence, we consider statistically dependent disruptions, allowing probabilities updates about non-probed components. After executing a solution plan, the

uncertainty realizes and the true reward is computed. The goal is to select a probing plan that maximizes the expected true reward. We reformulate the probing problem as a stochastic mixed-integer nonlinear bilevel problem with multiple followers and propose two solution approaches. The first uses the optimal value function reformulation, where conditional probabilities are expressed by a ratio of multilinear polynomials. This yields a large-scale problem with an exponential number of variables, which we address via a cutting-plane algorithm. The second approach applies a strong-duality reformulation when the second-stage problem is a linear program, representing conditional probabilities as maximum flow problems over a graph constructed by the scenario set of uncertainties. A specialized branch-and-bound algorithm exploits the resulting reformulation structure by solving the problem for each scenario in parallel. Computational experiments for the longest path problem show that probing a subset of the components can yield large improvements in the optimal value for small- to medium size instances.

4 - Decision Diagram-Based Cuts for Binary Bilevel Programs

Sebastián Vásquez, Carnegie Mellon University, Pittsburgh, PA, United States, Leonardo Lozano, Willem-Jan van Hoeve

Solving binary bilevel programs remains challenging due to the lack of strong, tractable relaxations. Recent work has embedded decision diagrams into the high-point relaxation to obtain exact extended reformulations and valid bounds. However, diagram size often limits scalability. We propose a new decision diagram-based framework for binary bilevel programs that uses diagrams as oracles to derive cuts directly in the original variable space. Building on existing approaches, we introduce new exact reformulations and show how to improve structured cuts. Moreover, we introduce a new extended diagram encoding that allows to retrieve stronger cuts and improve any valid cut. Computational results demonstrate the effectiveness of our approach.

1 - An Update to Optichat: Explaining Optimization Models Using Large Language Models

Can Li, Purdue University, West Lafayette, IN, United States, Hao Chen, Sai Madhukiran Kompalli

A significant obstacle to the practical deployment of optimization models is the challenge associated with helping practitioners comprehend and interpret these models. Our research group has been developing OptiChat, a chatbot powered by large language models, designed to explain optimization problems. The initial version of OptiChat supports a variety of functionalities, including diagnosing infeasibilities, conducting sensitivity analyses, offering counterfactual explanations, and answering general user queries. In this talk, we present recent updates to OptiChat, including integration with multiple LLM platforms, incorporation of interpretable decision rules, support for more complex counterfactual queries, and the generation of graph-based sensitivity insights. These enhancements aim to further bridge the gap between optimization model outputs and user comprehension.

2 - Llms for Cold-Start Cutting Plane Separator Configuration

Anders Wikum, Stanford University, Stanford, CA, United States, Connor Lawless, Yingxi Li, Madeleine Udell, Ellen Vitercik

Mixed integer linear programming (MILP) solvers ship with a staggering number of parameters that can have an outsized impact on the performance of the MILP solver, but are challenging to configure for all but expert optimization users. Existing machine learning (ML) approaches for solver configuration require solving thousands of related MILP instances during training, generalize poorly to new problem sizes, and often require implementing complex ML pipelines and custom solver interfaces that can be difficult to integrate into existing optimization workflows. In this paper, we introduce a new LLM-based framework to configure which cutting plane separators to activate for a given MILP problem using little to no training data. Our approach produces separator configurations based on characteristics of the instance, like a LaTeX formulation and natural language description, and is augmented by literature-based descriptions of the cutting plane separators available in a given solver. While individual configurations have a large variance in performance, we present a novel ensembling strategy that clusters and aggregates configurations to create a small portfolio of high-performing configurations. Our LLM-based methodology requires no custom solver interface, generates individual configurations with simple API calls that run in under a second, and can find a high-performing configuration by solving only a small number of MILPs. Numerical results show our approach is competitive with existing configuration approaches on a suite of classic combinatorial optimization problems and real-world datasets, using a fraction of the training data and computation time.

3 - Feasibility Versus Optimality in the Verification of Neural Networks Using Mixed Integer Linear Programming

Konstantinos Ziliaskopoulos, Auburn University, Auburn, AL, United States, Alice Smith

The formal verification of neural network properties presents significant computational challenges due to the non-convex nature of activation functions, particularly the Rectified Linear Unit (ReLU), which introduces binary decisions into the optimization model. Mixed-Integer Linear Programming (MILP) formulations offer a natural framework for modeling these networks by representing ReLU functions as complementary constraints with binary indicators, enabling rigorous verification guarantees and adversarial sample discovery. However, formulating neural networks as mathematical models comes with the cost of computational complexity that grows exponentially with network size. This research examines alternative MILP formulation approaches for neural networks. We explore the transformation of traditional optimization problems with distance metric objectives (e.g., L-infinity, L1 norms) into feasibility problems that search for adversarial examples within specified error tolerance bounds. Our methodology compares these approaches across multiple dimensions, including solution times, preprocessing effectiveness, objective formulation, and constraint structure. Additionally, we investigate pre-solving techniques for variable bound tightening and methods for eliminating redundant piecewise linear constraints before optimization. The study evaluates the interpretability of various objective function metrics and their use cases and examines misclassification rates after retraining models with adversarial samples. Through systematic comparison of these formulation strategies, this work contributes to the understanding of computational trade-offs between MILP formulation complexity, solution approach, and adversarial training frameworks in neural network verification.

4 - Equivamap: Leveraging LLMs for Automatic Equivalence Checking of Optimization Formulations

Haotian Zhai, The University of Texas at Austin, Austin, TX, United States, Connor Lawless, Ellen Vitercik, Leqi Liu

A fundamental problem in combinatorial optimization is identifying equivalent formulations. Despite the growing need for automated equivalence checks—driven, for example, by *optimization copilots*, which generate problem formulations from natural language descriptions—current approaches rely on simple heuristics that fail to reliably check formulation equivalence. Inspired by Karp reductions, in this work we introduce *Quasi-Karp equivalence*, a formal criterion for determining when two optimization formulations are equivalent based on the existence of a mapping between their decision variables. We propose *Equivamap*, a framework that leverages large language models to automatically discover such mappings for scalable, reliable equivalence checking, with a verification stage that ensures mapped solutions preserve feasibility and optimality without additional solver calls. To evaluate our approach, we construct *Equivamap*, the first open-source dataset of equivalent optimization formulations, generated by applying transformations such as adding slack variables or valid inequalities to existing formulations. Empirically, *Equivamap* significantly outperforms existing methods, achieving substantial improvements in correctly identifying formulation equivalence.

5 - Heuristics for a Vehicle Routing Problem with Size Constraints in Agricultural Applications, Including An LLM-Based Approach

Jung Yun Bae, Michigan Technological University, Houghton, MI, United States, Hyeseon Lee

Vehicle routing is a critical challenge in coordinating heterogeneous multi-robot systems for agricultural applications. This research addresses a vehicle routing problem in automating lavender harvesting, where robots of varying sizes must collaboratively navigate complex field layouts to efficiently complete given tasks.

We propose two heuristic approaches to address a specific problem of vehicle routing for lavender harvesting. The first approach utilizes a Large Language Model (LLM) to generate harvesting plans. Providing the LLM with small-scale examples and iteratively refining prompts with detailed descriptions of task attributes, robot capabilities,

and environmental conditions produces feasible task allocations and paths for each robot while minimizing overall operational time. The second approach employs a greedy heuristic algorithm, which starts with an initial feasible solution and iteratively improves it by optimizing task allocation and robot paths while ensuring all constraints are satisfied. This method guarantees feasibility by directly incorporating task requirements and robot constraints into its optimization process.

Both approaches are validated through simulations of lavender fields with varying robot sizes, environmental layouts, and numbers of robots and tasks. The results demonstrate the effectiveness of these methods in achieving efficient routing for heterogeneous multi-robot systems. This work highlights the potential for these approaches to advance automation in lavender harvesting, contributing to increased efficiency and sustainability in agricultural operations, further considering fuel and payload constraints as well as required harvesting techniques.

2 - An Old Theorem and A Chaotic World

Yves Smeers, Université Catholique de Louvain, Mont-Saint-Guibert, Belgium

Based on “Marginal Pricing and the Energy Crisis: where should we go?” I. Abada, A. Ehrenmann and Y. Smeers; forthcoming in “Energy Economics”. Abstract: The old theorem is due to M. Boiteux (1960). It states the equality between short and long-term marginal costs when capacities are adapted. The chaotic world is the one where shocks prevent capacities to be adapted, which seems to become the new standard. The question is what remains from Boiteux’s theorem when his fundamental assumption of adapted capacities is no longer satisfied and what are the implications for capacity development and capacity expansion models. These ideas developed from the energy crisis in Europe after the eruption of the war in Ukraine; they may remain relevant today and extend beyond the power sector.

1 - Data-Driven Successive Linearization for Optimal Voltage Control

Wenqi Cui, New York University, New York City, NY, United States, Steven Low

High variability of solar PV and sudden changes in load (e.g., electric vehicles and storage) can lead to large voltage fluctuations. In recent years, a number of advanced controllers have been designed to optimize voltage control. However, these controllers typically rely on fixed linear approximations of voltage dynamics. As a result, the solutions may become infeasible when applied to the actual voltage behavior governed by nonlinear power flow equations, particularly under heavy power injection from distributed energy resources. This talk will describe a data-driven successive linearization approach for voltage control under nonlinear power flow constraints. By leveraging the fact that the deviation between the nonlinear power flow solution and its linearization is bounded by the distance of the operating point, we perform data-driven linearization around the most recent operating point. Convergence of the proposed method to KKT points is established by exploiting the convexity of the objective function and the structural properties of the nonlinear constraints. Case studies show that the proposed approach achieves fast convergence and adapts quickly to changes in net load.

2 - Data as a Requisite for Learning in Power Systems

Rabab Haider, University of Michigan, Ann Arbor, MI, United States

Machine learning models have been developed for a wide variety of power system applications. In many settings where real data is limited or unavailable, machine learning models are trained using synthetic data sampled via different strategies. Our preliminary results show that the methodologies employed to generate these datasets greatly influence learning efficacy. This result is not surprising. Specific to power systems, different data streams, including topological data, generator and load characteristics, and voltage measurements impact the ability for neural networks to learn the underlying power flow representation. Data augmentation approaches, including active and importance sampling, are well established in literature, but may be limited if the data streams themselves are limited. Recommendations for dataset generation and augmentation may be derived, and additional work to develop datasets for learning in power systems is needed.

3 - Optimistic Bias in Data-Driven Risk Estimation and Optimization

Utsav Sadana, Université de Montreal, Montreal, QC, Canada, Erick Delage, Angelos Georghiou

The entropic risk measure is commonly used in high-stakes decision-making to account for tail risks. Empirical entropic risk estimator that replaces expectation in the entropic risk measure with sample average underestimates true risk. To correct this bias, a strongly asymptotically consistent bootstrapping procedure is proposed that fits a distribution to the data and then estimates the bias in the empirical estimator via bootstrapping. Two methods are proposed to fit a distribution to the data, a computationally intensive one that fits the distribution of empirical entropic risk, and a simpler one that fits the tail of the empirical distribution. The approach is applied to a distributionally robust entropic risk minimization problem with type- ∞ Wasserstein ambiguity set, demonstrating improved calibration of size of the ambiguity set using debiased validation performance.

4 - Smart Auctions for Smart Grids: Learning-enabled Local Energy Market Design

Lesia Mitridati, Technical University of Denmark, Kgs Lyngby, Denmark

Citizen energy communities and local energy markets offer a promising pathway to unlock the flexibility of consumers and prosumers. Yet, designing efficient and scalable consumer-centric energy markets remains challenging. Indeed, flexible consumers and prosumers often have heterogeneous preferences that go beyond purely financial considerations, including when and where energy is generated, how it is sourced, and even who they are trading with. Capturing these complex preferences over multiple energy attributes without placing unrealistic computational burdens on participants is key to building practical local energy markets.

This talk presents recent advances, fusing online learning and mechanism design to address these challenges. First, we introduce a novel framework that integrates hierarchical optimization with Thompson sampling to dynamically set optimal prices while simultaneously learning prosumer behaviors through observed responses. We then show how online learning techniques can support the design of scalable iterative combinatorial auctions that match complex supply and demand preferences over energy bundles.

Through realistic numerical studies across simulated energy communities, we demonstrate that these learning-enabled market mechanisms can quickly converge to efficient and fair allocations, while preserving prosumers' autonomy and minimizing communication overhead. Together, these results pave the way toward adaptive consumer-centric local markets for decentralized energy systems.

5 - Structured Learning for TIME Series Aggregation in Net-Zero Power Systems: from Simplex Theory to Scalable Optimization

Sonja Wogrin, Graz University of Technology, Graz, Austria, Yannick Werner, Luca Santosuosso, Beltran Castro Gomez

The transition to net-zero energy systems involves integrating renewables, flexibility technologies, and sector coupling - dramatically increasing the complexity of long-term energy system optimization models that depend on time series input data. The ERC-funded project *NetZero-Opt* proposes a novel time series aggregation (TSA) method that utilizes Dantzig's simplex algorithm for the identification of active constraint sets and provides performance guarantees.

In this presentation, we showcase how machine learning, grounded in simplex foundations, is leveraged within the *NetZero-Opt* framework to accelerate computational performance. We highlight two key applications: (1) using a classifier to predict active time-linking (e.g., ramping or storage) constraints in power system models. This prediction enables us to disaggregate large-scale linear programs and solve parallel submodels, significantly reducing computation times without compromising accuracy. (2) TSA is exact when you aggregate data points from the same set of active constraints, but it incurs an error when merging points from multiple active constraint sets. We use learning to identify optimal mergers to minimize the output error to leverage performance gains.

Together, these learning-based methods with theoretical underpinnings for TSA illustrate a new frontier in scalable optimization for energy system modeling.

1 - Conservation Incentive Design Under Uncertainty: a Stochastic Differential Game Approach with Asymmetric Information

Behnam Momeni, George Mason University, Fairfax, VA, United States, Shima Mohebbi

Water rights trading (WRT) is a market-based mechanism that promotes conservation in the management of water resources, particularly in response to water scarcity. In a voluntary WRT setting, water users, whose water rights were historically allocated and remain fixed, can temporarily lease or permanently sell them to other users or conservation organizations. This study designs conservation incentives using stochastic differential games with asymmetric information. The problem is set within a system involving three main networks of players: Non-Governmental Organizations (NGOs), groundwater users, and surface water users. The NGO aims to design incentive mechanisms that encourage water users to sell or lease their water rights in response to its offer. Following the NGO's offer, water users have three options: trade their water rights with the NGO, trade with other water users, or choose not to engage in trading. However, the NGO does not have perfect information about the individual water users, such as their initial willingness to participate in the offer or their value of water, while the users have more complete knowledge about their conditions. Additionally, some parameters, such as the actual water demand of users during each time interval (which may fluctuate due to factors like weather), remain uncertain for both the NGO and the users at the beginning of each time interval. Analyzing how these parameters affect the players' behavior is the foundation for the next step in the sensitivity analysis. Finally, The Red River basin serves as the case study.

2 - An Infinitesimal-Interval Approach to Markovian Coherent Risk Measures in Continuous Time

Jian Yang, Rutgers University, Newark, NJ, United States

We study the formation of the risk function which, in continuous time, assesses the risk borne by a decision maker who has coherent-risk attitudes and faces a finite-state Markov state process. In our limiting process involving ever finer partitions of time, risks are characterized by semi-derivatives that were introduced by Dentcheva and Ruszczyński (2018) to measure coherent risks' changes in response to random state oscillations. Interestingly, convexity of the risk-representing dual sets would play a pivotal role in our pursuit for convergence. The function achieved in the limit is validated by its satisfaction of an ordinary differential equation (ODE) that bears one unique solution. Our infinitesimal-interval approach has the added benefits of relying on only model primitives and providing a natural discrete-time approximation scheme. It can be applied to some cases involving continuous states as well, when transition probabilities are substituted by cumulant generating functions (CGFs). Both possess the "near proportionality to a small time increment" property.

3 - Spatial Decision-Making Under Markovian Dispersal: a Mixed-Integer Programming Approach

Chao Wang, University of Maryland, Cambridge, MD, United States, Jorge Sefair

We develop a spatial optimization framework for ecological corridor design under uncertain animal movement using a Spatial Absorbing Markov Chain (SAMC) model. This formulation captures probabilistic dispersal across fragmented landscapes, where the goal is to select a subset of spatial nodes that forms a movement corridor maximizing the likelihood of successful absorption into habitat patches, subject to budgetary, biological, and geometrical constraints. The objective function is non-additive and defined over transition-based absorption probabilities, leading to a substantially more complex solution structure than conventional deterministic or additive utility models. While the formulation does not fall under classical stochastic programming, it embeds ecological uncertainty via a Markovian process within a nonlinear mixed-integer programming framework, capturing spatial variability without relying on scenario-based enumeration. To address the model's nonconvexity and combinatorial scale, we design a tailored solution method that incorporates problem reformulations, warm-start initialization, valid inequalities, bound tightening heuristics, and variable reduction techniques. We demonstrate the model and algorithm on both synthetic testbeds and a real-world application involving Florida panther habitat connectivity. Results show our approach significantly outperforms commercial solvers and scales effectively to large, heterogeneous landscapes. This work offers a novel bridge between stochastic ecological modeling and large-scale spatial decision-making.

4 - Best-Response Dynamics Incorporated Zero-Regret Algorithm for Large-Scale Integer Programming Games with Application to Aquatic Invasive Species Prevention

Hyunwoo Lee, Virginia Tech, Blacksburg, VA, United States, Robert Hildebrand, Esra Toy, selina cai

This paper presents a scalable algorithm for computing the best pure Nash equilibrium (PNE) in large-scale integer programming games (IPGs). While recent advances in IPG algorithms are extensive, existing methods are limited to a small number of players, typically $n=2,3$. Motivated by a county-level aquatic invasive species (AIS) prevention problem involving 84 players -- we develop efficient and scalable algorithms that significantly extend the applicability of IPGs. Specifically, we propose the best-response dynamics incorporated zero-regret (BZR) algorithm, which leverages best-response dynamics (BRD) for rapid PNE identification and integrates BRD as a primal heuristic within the zero-regret (ZR) framework. This approach dramatically improves the scalability of IPG algorithms, allowing us to solve IPGs with up to 30 players in random datasets and the 84-player AIS prevention problem with Minnesota data. To model the AIS prevention problem, we introduce the Edge-weighted Budgeted Maximum Coverage (EBMC) game, a new class of IPG that has not been previously studied. We establish theoretical conditions for the existence of a PNE under both selfish and locally altruistic utility functions. Experimental results in EBMC games and knapsack problem games demonstrate that BZR significantly enhances ZR in both finding a PNE and identifying the best PNE, particularly in games with many players.

Co-Chair: Lingling Shi, Macmaster, Hamilton, ON, Canada

1 - Dismissal of Demand Dependence Disappoints and Deceives: the Case of Microgrid Generation and Storage Investments

Jiarui (Gary) Wei, University of Texas at Dallas, Richardson, TX, United States, Fariba Farajbakhsh Mamaghani, Metin Cakanyildirim

Microgrids (MGs) emerge as vital components of energy transition, offering local and low-cost solutions, e.g., for meeting the increasing demand of data centers and hence relieving the pressure on the grids. MGs, comprising of local generators, storage equipment and consumers, trade electricity with the grid through contracts specifying grid's purchase price. Determining optimal generation and storage capacities for MGs presents significant challenges due to uncertainties in the demand and market price, and specifically their dependence. We incorporate uncertainties and dependences when evaluating and maximizing MG profits. Moreover, we present closed-form solutions for optimal generation and capacity levels. To formulate dependence, we rely on a positively associated representation of demand and price pair. We include empirical analysis to showcase this dependence and a realistic case study along with a sensitivity analysis. We identify weak conditions for generation and storage optimization to bypass traditional dynamic programming approaches. We obtain two major and novel results: ignorance of demand dependence (of price) artificially inflates profits and yields lower optimal capacities. We identify the type of microgrid-grid contract and positively associated demand-price pairs as drivers of our results by studying an alternative contract and negatively associated pairs. We package our key insights as takeaways and customize them for the MG stakeholders. MG operators should capture demand dependence to avoid financial disappointments. In contrast, these operators might ignore demand dependence when negotiating with financial institutions to secure favorable financing terms.

2 - Remanufacture OR Salvage? Reverse Logistics Optimization for Wind Turbines with Imperfect Sorting

Siqiang Guo, University of Missouri-St. Louis, St. Louis, MO, United States, Haitao Li

This study examines reverse logistics decisions for retired wind turbines under imperfect on-site sorting. We model the classification errors using a confusion matrix and develop a cost-minimization framework that captures key trade-offs among remanufacturing profit, salvage value, transportation cost, and sorting accuracy. Closed-form optimality conditions are derived for different sorting scenarios, revealing when remanufacturing is economically justified. Numerical experiments validate the analysis and show how system performance changes with turbine condition and sorting quality. The study addresses a key gap in the literature by jointly considering imperfect sorting and high transportation costs in wind turbine recovery.

3 - Integrating EV Charging and Discharging into Power Grid Through Bilateral Negotiation

Linqiu Li, University of Science and Technology of China, Hefei, China, People's Republic of, Yun Fong Lim, Kai Pan

To deal with demand uncertainty on a power grid, a power plant with limited ramping capability can collaborate with an electric vehicle (EV) company. With proper charging and discharging prices, the EV company voluntarily withdraws electricity from or returns electricity to the power grid in suitable phases. We model the two parties' interactions as a bargaining game on the prices, followed by the EV company's charging and discharging problem and the power plant's electricity generation problem. To solve this bargaining game, we propose a novel "Guess and Verify" approach. Specifically, we first find an optimal solution within a restricted price set in which the two parties' total cost is minimized, and then verify its global optimality. Under an equilibrium contract, we find that the power plant can reduce its expected cost from the collaboration. This is because the EV company fully charges in a low electricity demand phase, reducing the power plant's curtailment cost, and fully discharges to the power grid in a high electricity demand phase, lowering the power plant's electricity generation cost. Based on real data, our numerical experiments suggest that the EV company's charging and discharging can substantially harmonize the power flow within the grid and save significant cost, especially when the electricity demand gap across different phases increases or the power plant's ramping capability decreases. Surprisingly, the EV company's percentage cost saving can exceed 100%, implying that it can make a profit from the collaboration. For the power plant, the percentage cost saving is 2-7%.

4 - Strategic Deployment of Electric Vehicle Charging Infrastructure in South Korea

Na Rea Cho, Wichita State University, Wichita, KS, United States, JINAH YANG, Zahra Ziaei

While electric vehicles (EVs) have garnered worldwide attention, the lack of adequate charging infrastructure remains a significant hurdle to widespread adoption. To address this challenge and support the South Korean government's goal of accelerating EV adoption rates, this study develops a data-driven approach to optimize the placement and capacity of EV chargers in a planned city in South Korea. This study first forecasts EV charging demand based on 7 years of annual demographic attributes and historical charging data. Using these demand projections, we then determine the optimal locations and capacities of charging stations while accounting for government regulations and investment considerations. Our findings identify key drivers influencing infrastructure investment and provide insights into the broader implications of EV charging deployment. Additionally, a case study using data from a Korean city validates the effectiveness of our approach and demonstrates its practical applicability in guiding sustainable urban mobility planning.

1 - Uncovering Illicit Supply Chains with Network Optimization: An Illustration Using Cocaine Flow in the United States

Courtney Paulson, University of New Hampshire, Durham, NH, United States, Margret Bjarnadottir, Eunseong Jang, Greg Midgett

Despite increasing crackdowns on illegal drugs, the illegal drug trade in the U.S. alone accounted for approximately \$500 billion in 2024. Combating illicit activities presents a unique challenge for law enforcement officials across the globe, primarily because by their nature, illicit networks are not known or directly observable. Illicit drugs follow hidden supply chains, forcing analysts to rely on secondary data to estimate patterns and movement. This proxy data is naturally limited, inconsistent, and highly variable. The bigger concern for modelers, however, is that these supply chains have no intrinsic ground truth on which to evaluate or train network models. To address these concerns, we develop a novel data-driven optimization approach to combine known data (e.g., law enforcement drug seizure data) with underlying estimation data (e.g., illegal drug fatalities) to maximize learning even with noisy and inconsistent illicit network data. We demonstrate our approach using real-world data on U.S. cocaine seizures and undercover purchases, which we combine with data gathered on overdose deaths. This allows us to derive network structures that are consistent with our data sources, validated using anecdotal data. We further show that we can augment the consistent mathematical modeling of these networks by varying optimization parameters, which create multiple networks based on comparative underlying structures. In the absence of a ground truth, these differing base models offer unique insights for law enforcement agents and governmental policymakers looking to develop forward-thinking strategies to address increasingly complex illicit networks.

2 - Agent-Based Modeling of Opioid use and Harm Reduction Strategies in Community Settings

Melika Jahan Beikloo, Clemson University, Clemson, SC, United States, Hyojung Kang, Mary Beth Kurz, Bryan Lee Miller, Thomas Sharkey, Emily Suiter

The opioid crisis remains a serious public health and criminal justice challenge in the United States, with synthetic opioids like fentanyl contributing to a sharp rise in overdose deaths and the situation further worsened by cuts to addiction treatment funding at state and federal levels. Addressing this complex issue requires tools that can capture the dynamic interactions between individuals, drug markets, and intervention efforts at the community level.

In this work, we present an evolving agent-based modeling (ABM) framework that simulates opioid use progression, drug distribution, and potential harm reduction strategies. Our model includes multiple agent types—such as non-users, opioid users, law enforcement, healthcare systems, and drug dealers—and allows for behavioral transitions, movement, and interactions, such as drug transactions or peer influences that affect individual behavior. We take an iterative approach to model development, continuously refining structure, assumptions, and complexity.

By modeling these dynamics, we aim to support ongoing efforts to better understand opioid-related outcomes and inform the design of effective, data-driven interventions.

3 - Unifying Fragmented Human Trafficking Data: Structural Insights from Ctdc and Unodc Using Ergms

Meng-Hao Li, George Mason University, Arlington, VA, United States, Naoru Koizumi

Both the Counter-Trafficking Data Collaborative (CTDC) and the United Nations Office on Drugs and Crime (UNODC) provide critical data on human trafficking. However, each reflects distinct reporting biases: CTDC captures cases involving victims who receive assistance from partner organizations, while UNODC relies on law enforcement and judicial statistics. These different reporting methods can lead to incomplete and biased views of human trafficking structures due to underreporting or selective detection.

We address this challenge by employing Exponential Random Graph Models (ERGMs) to compare country-level trafficking networks derived from each dataset. By incorporating structural dependencies and node-level covariates, ERGMs allow us to examine whether the two trafficking networks are shaped by similar formation processes. While this comparison highlights structural divergence between datasets, it does not resolve inconsistencies in how trafficking flows are represented.

To bridge this gap, we use a pooled ERGM, a form of multi-network ERGM that jointly models the CTDC and UNODC networks. This approach constrains both datasets to share the same structural parameters while allowing each to differ in baseline density. In doing so, it harmonizes heterogeneous sources and recovers consistent cross-dataset edge patterns while accounting for both structural and reporting heterogeneity. This strategy allows us to treat CTDC and UNODC not as competing accounts, but as complementary views of the same underlying trafficking structure.

4 - Organ Trafficking and Illicit Financial Flows: a Global Study of Kidney Price Spreads

Neelam Shukla, George Mason University, Arlington, VA, United States, Olzhas Zhorayev, Zifu Wang, Melis Ozdemir, Momo Toyoda-Tun, Meng-Hao Li, Naoru Koizumi

The illegal organ trade remains a significant global issue driven by severe shortages in legitimate organ supplies. In 2017, the Global Financial Integrity (GFI) estimated that kidney buyers paid between \$50,000 and \$120,000 per organ, while sellers received less than 10% of this amount. The GFI report primarily relies on aggregated estimates from official sources and lacks detailed transaction-level data, making it difficult to understand the specific factors behind these large price differences. This study aims to elucidate the factors influencing the price differential and construct a novel, transaction-level dataset of kidney trafficking. We systematically identified 978 kidney trafficking-related news articles (2000-2022) using LexisNexis and manually extracted illicit financial data (buyer payments, seller receipts, broker and surgeon fees, transaction and surgery locations). We also explored the use of Llama3.3-70B to extract prices, although the prediction remained poor due to the complex nature of transactions. The final dataset includes 96 transactions involving buyers from 46 countries and 124 involving sellers in 76 countries. Empirical analysis revealed that buyers paid an average of \$76,210 per organ, up to \$300,000, while sellers received an average of \$7,290, with some receiving as little as \$45. This 90% gap aligns with GFI's estimates. We further explored how national factors (e.g., income levels, income inequality, enforcement intensity, rule of law, corruption, social capital, and healthcare accessibility) influence the price spread and found some country-level variation. Overall, this study provides an evidence-based foundation for more targeted international policy responses aimed at reducing exploitation in illicit organ transactions.

Optimization for Statistics and Learning

Invited Session

OPT: Machine Learning

Chair: Yao Xie, Georgia Institute of Technology, Atlanta, GA, United States

1 - A Variational Inequality Approach to Nonlinear Tomographic Reconstruction

Kabir Verchand, University of Southern California, Los Angeles, CA, United States, Ashwin Pananjady

We consider the problem of signal reconstruction for computed tomography (CT) under a nonlinear forward model that accounts for exponential signal attenuation, a polychromatic X-ray source, general measurement noise (e.g. Poisson shot noise), and observations acquired over multiple wavelength windows. We develop a simple iterative algorithm for single-material reconstruction, which we call EXACT (EXtragradiant Algorithm for Computed Tomography), based on formulating our estimate as the fixed point of a monotone variational inequality. We prove guarantees on the statistical and computational performance of EXACT under practical assumptions on the measurement process. We also consider a recently introduced variant of this model with Gaussian measurements, and present sample and iteration complexity bounds for EXACT that improve upon those of existing algorithms. We apply our EXACT algorithm to a CT phantom image recovery task and show that it often requires fewer X-ray projection exposures, lower source intensity, and less computation time to achieve similar reconstruction quality to existing methods.

2 - Rectangularity and Duality of Distributionally Robust Markov Decision Processes

Yan Li, Texas A&M University, College Station, TX, United States, Alexander Shapiro

The main goal of this paper is to discuss several approaches to formulation of distributionally robust counterparts of Markov Decision Processes, where the transition kernels are not specified exactly but rather are assumed to be elements of the corresponding ambiguity sets. The intent is to clarify some connections between the game and static formulations of distributionally robust MDPs, and delineate the role of rectangularity associated with ambiguity sets in determining these connections.

3 - E-Minimax Solutions of Statistical Decision Problems via the Hedge Algorithm

Lezhi Tan, Management Science and Engineering Department, Stanford University, Stanford, CA, United States, Andrés Aradillas Fernández, Jose Blanchet, Jose Luis Montiel Olea, Chen Qiu, Jörg Stoye

We present an algorithm for obtaining ϵ -minimax solutions of statistical decision problems. We are interested in problems where i) the statistician is allowed to choose randomly among I decision rules, and ii) the statistical model may have a parameter space with infinitely many elements. The minimax solution of these problems admits a convex programming representation over the $(I - 1)$ -simplex, and the algorithm suggested herein to obtain an ϵ -approximation of the minimax solution is a version of mirror subgradient descent, initialized with uniform weights and stopped after a finite number of iterations. The resulting iterative procedure is known in the computer science literature as the Hedge algorithm (a particular case of the Multiplicative Weights update method) and it is used in algorithmic game theory as a practical tool to find approximate solutions of two-person zero-sum games. We apply the suggested algorithm to different minimax problems in the econometrics literature. An empirical application to the problem of optimally selecting sites to maximize the external validity of an experimental policy evaluation illustrates the usefulness of the suggested procedure.

4 - Necessary Optimality Conditions in Multiple Hypotheses Testing Under Exact Family-Wise Error Rate Control -- a Path to Fast Computing

Prasanjit Dubey, ISyE Georgia Tech, Atlanta, GA, United States, Xiaoming Huo

In multiple hypotheses testing problem, the computation of the most powerful test is numerically challenging. In the state-of-the-art, the searching for the most powerful test can be done via solving a constrained optimization problem. The dual problem has been derived and strong duality has been established in a very general sense. However, solving the dual problem is still an open question and could result in an exhaustive search, which is not numerically efficient. In this paper, under the exact family-wise error rate control, we proved some necessary conditions for the optimizer of the dual problem. These necessary conditions can lead to coordinate-wise fast algorithms, which may result in numerically efficient algorithms to solve the dual problem, which consequently solve the primal problem for identifying the most powerful test. We prove the linear convergence of our algorithm (that is, the computational complexity of our proposed algorithm is proportional to the logarithmic of the reciprocal of the target error). To the best of our knowledge, this is the first time such a fast algorithm is proposed for finding a most powerful test with family-wise error rate control.

5 - Statistical Estimation via Monotone Variational Inequality for Generalized Linear Models and Generalized Additive Models

Jonghyeok Lee, Georgia Institute of Technology, Atlanta, GA, United States

We propose a statistical estimation framework for generalized linear models (GLMs) based on variational inequalities (VI). Unlike the classical MLE, the VI estimator only requires the link function to satisfy a weak condition (strong Minty's condition), allowing broader applicability even for non-monotone link functions. We establish non-asymptotic estimation error bounds that match or improve upon those of MLE, while relying on weaker assumptions. Furthermore, we identify principles for designing link functions that yield sharper statistical rates and improved algorithmic efficiency. Building on these insights, we develop gradient-based and stochastic iterative methods with provable convergence guarantees. Our results demonstrate that VI estimation provides a flexible alternative to MLE, with advantages in both theoretical guarantees and practical performance across GLMs.

Facility Location Modeling for Critical Infrastructure

Invited Session

Location Analysis

Chair: Amir Hossein Moadab, Washington State University, Pullman, WA, United States

1 - Hub Location Problem with a Mixed Green Fleet

Okan Dukkanci, European University Viadrina, Frankfurt (Oder), Germany, James Campbell, Achim Koberstein

This study presents a new hub location problem with a mixed fleet of vehicles, including diesel-based vehicles, electric vehicles, and unmanned aerial vehicles. Each vehicle type has a different cost structure, payload capacity, and traveling range. The objective function minimizes the sum of the recharging (or refuelling) cost, driver cost, fixed vehicle cost, and waiting cost for vehicles and drivers at recharging stations. While the transportation cost (including the recharging cost, driver cost, and vehicle cost) depends on the traveled distance, the recharging fee and waiting cost depend on the number of visits to recharging stations. We develop a mixed-integer linear programming formulation with preprocessing rules and also propose a relax-and-fix heuristic approach. The computational experiments are conducted over well-known CAB and TR data sets, and also a new German data set. The computational results evaluate the performance of the relax-and-fix heuristics and analyze the impact of using different mixed fleets, complete hub networks, different cost structures, and a hypothetical drone with a larger payload capacity and a longer flying range. Results show how the optimal fleet mix, in particular the use of electric vehicles and drones, and the optimal network vary around the world, as these depend on the geographic scope of the services, the distribution of nodes and arc lengths, and the relative costs for fuel (electricity or diesel) and labor.

2 - Citywide Orchestration of Electrical Vehicle Battery Swapping

Zhiyuan Wang, Tsinghua University, Beijing, China, People's Republic of, Xian Guo, Wei Qi, Lun Ran

Electrical vehicle (EV) battery swapping has been developing rapidly in recent years. Despite the significant increase in the number of stored batteries within swapping service systems, mismatches between swapping demand and available batteries remain common and still unresolved. Coordinating the uneven spatial demand and battery inventory, which referred to as spatial coordination, is challenging. One potential solution to the spatial coordination issue arises from the rapid advancement of autonomous driving technology in electric vehicles: coordinated swapping, where EVs perform battery swaps at designated stations based on realized demand, with scheduling managed by a centralized service platform. However, it remains unclear how to design an infrastructure network for coordinated swapping or whether such an approach would lead to cost or battery savings. This paper investigates this emerging urban infrastructure network. Specifically, we model the operations of battery swapping stations using stochastic inventory theory and propose a two-stage distributionally robust optimization model for the joint location and capacity planning of a citywide battery swapping station network. We also propose two alternative strategies in battery swapping designed for specific scenarios, reformulating them as mixed-integer second-order cone programmings. In a numerical study, we validate our algorithm's efficacy using classic transportation data and compare the performance of the three strategies with real transportation data from Beijing. Our findings indicate that the coordinated swapping outperforms the other two strategies in terms of spatial coordination of swapping demand, thanks to its flexibility and economies of scale as the battery swapping network expands.

3 - Optimizing Public Access Automated External Defibrillators (Aed) Deployment Using Smartphone Dispatch Apps

Yifan Wu, Texas A&M University, College Station, TX, United States, Joseph Geunes, Xiaofeng Nie

Motivated by emerging urban applications in commercial, public-sector, and humanitarian logistics, we revisit continuous p-hub location problems under the L1 metric, where several facilities are to be located in a continuous space such that the expected minimum Manhattan travel distance from a random service provider to a random receiver through exactly one hub facility is minimized. Firstly, some closed-form results are derived for one-dimensional cases and two-dimensional cases up to two hubs. Secondly, we propose a simulation-based approximation method for problems with more than two hubs in two-dimensional cases. Finally, we apply our method to a case study on optimizing public access defibrillator locations using smartphone dispatch Apps.

4 - From Charging Costs to Infrastructure: a Cost-Informed Facility Location Model for EV Charging Under Operational Uncertainty

Ehsan Mahyari, The University of Scranton, Scranton, PA, United States

This research presents a novel integration of stochastic operational decision-making into strategic infrastructure planning for electric vehicle (EV) charging systems. Building on our approximate dynamic programming (ADP) framework for managing heterogeneous EV fleets at multi-connector depots, we propose a cost-informed facility location model that leverages operational insights to determine (i) the number of charging depots, (ii) the configuration of chargers at each site, and (iii) their optimal geographic placement. Unlike traditional facility location models that rely on static demand and deterministic costs, our approach embeds ADP-based cost evaluations within a multi-scenario optimization framework. For each candidate site and fleet service region, we simulate the ADP-managed operations under stochastic EV arrival patterns, variable electricity pricing, and charger availability. These simulations yield robust cost-to-serve estimates that inform the facility location decisions, enabling planners to minimize long-run charging costs while meeting service-level guarantees and grid constraints. The resulting model captures the interplay between operational policy and infrastructure design, allowing Charging-as-a-Service (CaaS) providers and public agencies to identify infrastructure configurations that are both resilient and cost-effective under real-world uncertainty. Numerical experiments based on urban and regional fleet scenarios demonstrate that the proposed approach significantly reduces total system cost and unmet demand compared to decoupled or static planning methods.

5 - Disaster Sheltering Network Design Prioritizing Welfare Enhancement and Public Health Protection

Mohamed Salama, Purdue University, West Lafayette, IN, United States, Min Kyung Lee, Yuehwen Yih

Although public shelters are crucial for safeguarding disaster survivors, many individuals risk their safety by refusing to evacuate. This is often due to the inferior conditions typically found in public shelters, such as crowding, continuous lighting, lack of privacy, and safety apprehensions, combined with the absence of alternative sheltering options. Additionally, the risk of infectious disease transmission, such as tuberculosis and COVID-19, further discourages seeking refuge in these facilities. To

address these issues, this study introduces a four-echelon network design aimed at providing small-capacity shelters that enhance welfare and public health. A two-stage stochastic mixed-integer linear programming model is developed to optimize the selection of opening nodes across the four echelons under various disaster scenarios, in addition to determining the associated logistical operations. This model considers the tradeoff between maximizing welfare-enhanced sheltering occupancy and minimizing related costs. To efficiently solve the model and offer practical benefits, a novel problem-specific scenario-based cutting-plane algorithm is developed.

SpORts II

Invited Session

spORts

Chair: Keith Willoughby, University of Saskatchewan, Saskatoon, SK, Canada

1 - Ranking Sports Teams, Teaching Analytics, and Reaching the Public

Laura Albert, University of Wisconsin-Madison, Madison, WI, United States

In this talk, we will discuss how to rank sports teams using a Markov chain-based methodology, which has been used on Badger Bracketology to rank college football, college basketball, and NFL teams. We will present the ranking methodology, with a special focus on its application to the College Football Playoff. Additionally, this talk will highlight how sports analytics can engage students and connect with the public.

2 - Performance Under Pressure: Soccer Penalties and Basketball Free Throws

Nils Rudi, Yale School of Management, New Haven, CT, United States, Andrea Wang

This work considers generative-model approaches to high-pressure scoring events in soccer penalty shootouts and basketball free throws. By specifying a probabilistic process for how each shot arises—capturing latent abilities, sequential decision steps, and contextual pressure—the models can leverage structural assumptions to achieve meaningful inference even with limited data. Bayesian estimation is employed to propagate uncertainty through to latent skill estimates. We will highlight the conceptual parallels between the two sports and discuss how generative assumptions can support performance analytics and strategic decision-making when observations are limited.

3 - A Swimming Coach's Beautiful Mind? Lineup Strategies and Measuring a Swimmer's Value

Matthew Bailey, Bucknell University, Lewisburg, PA, United States

We present a game-theoretic framework to strategically select optimal swim team lineups for competitive meets. By integrating mathematical modeling and game theory principles, we address the decision-making process involved in creating meet lineups by assigning athletes to their events. We seek to maximize the team's expected points, taking into consideration each swimmer's strengths, weaknesses, and event preferences relative to the opponent's potential lineups. The study further analyzes the marginal impact of each selected swimmer on the overall team performance. Our research contributes to a more informed and strategic approach offering decision support for assembling swimming team lineups, while offering coaches valuable insights into maximizing their team's competitive advantage.

4 - The Source of All Frustration: Exploring Schedule Inequities in Canadian Football

Keith Willoughby, University of Saskatchewan, Saskatoon, SK, Canada

Teams in professional sports like baseball, basketball, and hockey may play multiple games per week. However, football teams typically compete in at most one game during a week. Games in the Canadian Football League (CFL) are generally scheduled on Thursday, Friday, Saturday, and Sunday of each week. This forces CFL franchises to play with more (or less) days rest than their opponents. We have engaged with the CFL in building operations research models to inform schedule creation and can confirm that teams view “short weeks” as pain points in the scheduling process. Exploring two decades worth of league schedules, we find some evidence that teams with more days rest than their opponents experience a competitive advantage.

5 - Does Fatherhood Impact the Performance of Professional Cyclists?

Jeroen Belien, KU Leuven, Brussel, Belgium, Anke Baetens, Filip Van den Bossche

This study examines the impact of fatherhood on the performance of professional road cyclists. Fixed effects panel regression is used to compare cycling performance over a period after having a child with the performance in the same period the year before. The results of this study may help to provide better psychological and athletic support for recent fathers and are potentially relevant to contexts other than professional (cycling) sport.

Decision-Making Under Uncertainty: Robustness, Fairness, Interpretability, and Personalization

Invited Session

OPT: Optimization Under Uncertainty

Chair: Phebe Vayanos, University of Southern California, Los Angeles, CA, United States

Co-Chair: Ryan Edmonds, University of Southern California, Los Angeles, CA, United States

1 - Learning Confounding Robust Optimal Risk Scores from Observational Data

Yingxiao Ye, University of Southern California, Los Angeles, CA, United States, Andres Gomez, Cagil Kocyigit, Sina Aghaei, Phebe Vayanos

We consider the problem of learning, from observational data, a logistic regression model to predict the risk of an adverse outcome under no treatment. This problem arises routinely in public health and the social sciences, e.g., to help prioritize individuals for scarce resources or services. The vast majority of the literature assumes unconfoundedness, requiring that we have access to all individual characteristics that were used historically to decide on treatment assignments. However, this assumption often fails to hold in practice, where treatment decisions are often the result of a combination of observed and unobserved characteristics with e.g., conversations that are not recorded anywhere impacting decisions. In this research, we propose a logistic regression-based risk prediction model that is robust to potential unobserved confounders. We demonstrate the effectiveness of our approach on both synthetic and semi-synthetic data, showing that our approach achieves better performance compared to both baseline and state-of-the-art approaches. We also illustrate the power of our approach on the problem of learning a vulnerability score for prioritizing individuals experiencing homelessness for scarce resources and services based on the real data from the LA County Homeless Management Information System.

2 - Learning Robust Prescriptive Trees Under Unobserved Confounders

Ryan Edmonds, University of Southern California, Los Angeles, CA, United States, Phebe Vayanos

We consider the problem of learning prescriptive trees that are robust to unobserved confounders in historical data. This problem arises frequently in high stakes settings such as public health and housing allocation, where policy decisions made in the past may have depended on factors not present in the historical data (i.e., personal interactions between social workers and individuals receiving treatment). These domains also frequently require that learned policies be interpretable, as opposed to black box methods. We propose a method for learning robust prescriptive trees using inverse propensity weighting. In particular, we formulate the problem as a max-min optimization, with the goal of learning a tree robust to adversarial choices of confounding. We show that under some assumptions on how unobserved confounders can affect the true propensity weights, our optimization can be recast as a single stage mixed integer optimization problem. Our formulation has the ability not only to model domain specific constraints, in accordance with previous work on decision trees, but also to model domain specific assumptions on confounders.

3 - A Maximum Likelihood Approach to Randomized Trees

Zhiyuan Sun, University of California, Los Angeles, Los Angeles, CA, United States, Velibor Misic

Randomized trees, unlike traditional deterministic trees, offer a novel framework for predictive modeling by splitting data points with a probability that is determined by their feature vectors and specific parameters at each node. This paper introduces a smooth non-convex Maximum Likelihood Estimation (MLE) problem for learning the parameters of randomized trees from data. We establish that optimizing over randomized trees is theoretically equivalent to optimizing over deterministic trees. We further develop an algorithm that leverages the Expectation-Maximization (EM) method to efficiently optimize the parameters of randomized trees. We theoretically prove the consistency of our randomized tree MLE problem and develop generalization guarantees for the log likelihood of randomized trees by analyzing the Rademacher complexity. Our numerical experiments demonstrate the effectiveness of our method in improving predictive performance over classical top-down induction methods such as CART over a variety of binary and multiclass classification datasets.

4 - Equitable Auction Design: with and Without Distributions

Napat Rujeerapaiboon, National University of Singapore, Singapore, Singapore, Ruiqin Wang, Cagil Kocyigit

We study a mechanism design problem where a seller aims to allocate a good to multiple bidders, each with a private value. The seller supports or favors a specific group, referred to as the minority group. Specifically, the seller requires that allocations to the minority group are at least a predetermined fraction (equity level) of those made to the rest of the bidders. Such constraints arise in various settings, including government procurement and corporate supply chain policies that prioritize small businesses, environmentally responsible suppliers, or enterprises owned by historically disadvantaged individuals. We analyze two variants of this problem: stochastic mechanism design, which assumes bidders' values follow a known distribution and seeks to maximize expected revenue, and regret-based mechanism design, which makes no distributional assumptions and aims to minimize the worst-case regret. We characterize a closed-form optimal stochastic mechanism and propose a closed-form regret-based mechanism, and establish that the ex-post regret under the latter is at most a constant multiple (dependent on the equity level) of the optimal worst-case regret. We further quantify that this approximation constant is at most 1.31 across different equity levels. Both mechanisms can be interpreted as set-asides, a common policy tool that reserves a fraction of goods for minority groups. Furthermore, numerical results demonstrate that the stochastic mechanism performs well when the bidders' value distribution is accurately estimated, while the regret-based mechanism exhibits greater robustness under estimation errors.

5 - Prefactual Recommendation by Bayesian Preference Elicitation

Viet Anh Nguyen, Chinese University of Hong Kong, Hong Kong, Hong Kong

Algorithmic prediction models increasingly influence high-stakes decision-making, highlighting the need to empower individuals to overturn unfavorable predictions. Prefactual recommendations, or algorithmic recourses, provide actionable guidance to help applicants achieve favorable algorithmic predictions with a minimal effort in modifying their features. However, most existing methods assume that all applicants share the same cost function and do not account for subjective differences in the cost function between applicants. To address these shortcomings, we propose the Prefactual Recommendation by Bayesian Preference Elicitation (PROBE) framework, which personalizes prefactual recommendations by learning an applicant's cost preferences. PROBE consists of two principal components: Bayesian preference elicitation and graph-based risk-averse recommendation generation. In the preference elicitation stage, PROBE learns a Mahalanobis approximation of the applicant's cost function through an interactive question-answering scheme. In each round, the most informative questions are selected by maximizing the mutual information between the applicant's response and the prior belief of the cost parameters. Upon observing the applicant's responses, the posterior belief is updated using a variational Bayesian approach, which balances the prior-posterior distortion and the alignment of the posterior with the observed responses. To generate prefactual recommendations, PROBE constructs a graph based on available data to capture actionability constraints and assigns a stochastic edge cost by leveraging the terminal Mahalanobis posterior belief. PROBE then searches for an optimal mean-variance path from the applicant's current feature values to a node with a favorable prediction. This is a joint work with Lemn Kong, Marshal Sinaga and Anthony So.

Advances in Network Interdiction: Theories and Applications

Invited Session

OPT: Network Optimization

Chair: Thanakrit Piyachayawat, Texas tech university, Lubbock, TX, United States

1 - Robust Network Enhancement

Thanakrit Piyachayawat, Texas Tech University, Lubbock, TX, United States, Ningji Wei

Network systems such as critical supply chains, power grids, and water distribution systems are constantly facing challenges due to natural disasters and adversarial disruptions. Enhancements that attempt to improve the associated operational efficiency become critical and challenging due to uncertain factors such as economic fluctuations and investment inefficiency. In this work, we propose a general mathematical model for these network structures while mitigating uncertainties from multiple sources. Through this approach, we obtain effective and robust network enhancement plans that account for the performance range of the network structures, defined by their worst-and best-case scenarios. We develop exact solution methods using cut-generation techniques. To improve the scalability and efficiency, we develop an approximation method with performance guarantee. These findings offer promising results for tackling real-world network enhancement problems under uncertain factors.

2 - Protecting Humanitarian Logistics: An Interdiction Framework for Problems with Shared Resource Interdependencies

Rafal Muszalski, University at Buffalo, Buffalo, NY, United States, Jose Walteros

Modern supply and infrastructure systems are increasingly vulnerable to disruption, both accidental and adversarial, especially when protection and service operations must compete for limited resources. In this work, we study a class of **multi-stage interdiction games** that model such interdependent and adversarial settings through a finite, sequential, and alternating decision process between a *protector*, *attacker*, and *defender*. Specifically, we consider a **facility location allocation problem** in which a shared pool of resources, such as service crews or vehicles, must be allocated across two competing objectives: (1) fortifying regions against potential interdiction, and (3) delivering supplies to customers in the aftermath of an attack.

This inherently creates a **resource trade-off** between stages, where protection decisions made early in the game directly constrain the operational capabilities available for service delivery later. Moreover, interdiction actions taken in the second stage are adaptive to the observed protection policy, compounding the strategic complexity. We formalize this as a three-stage optimization game with interdependencies across non-consecutive stages, where early protection choices can render later service plans infeasible or suboptimal.

To solve these challenging problems, we propose an **exact combinatorial branch-and-bound framework** tailored to capture the structure of these interdependencies. Our approach efficiently explores the space of joint protection and service strategies under adversarial threat. We illustrate the effectiveness of our method through applications to **network-based facility allocation problems**, with relevance to **humanitarian logistics**.

3 - Network Interdiction with General Integer Variables

Anh Truong, University of Florida, Gainesville, FL, United States, Leonardo Lozano, Jorge Sefair

We study a network interdiction problem in which a defender seeks a minimum-cost flow through a capacitated, directed network, while an attacker aims to maximize this cost. The attacker disrupts the network through interdiction actions such as reducing arc capacities, increasing arc costs, or both. The attacker actions are modeled using general integer variables that capture the location and intensity of disruptions. We develop a single-level dual reformulation of the problem, strengthened with three families of valid inequalities, including enhancements tailored for instances with sparse flow and large arc capacities. To improve scalability, we integrate the reformulation with a progressive approximation scheme that reduces network size. Computational experiments on grid networks demonstrate the effectiveness of our approach, expanding the class of tractable network interdiction problems.

4 - An Exact Algorithm for the Bi-Objective Shortest Path Interdiction Problem

Tanner Staggs, University of Florida, Gainesville, FL, United States, Jorge Sefair

We study a shortest-path interdiction problem in which the adversary's behavior (inner level) is modeled as a bi-objective shortest path problem (B-SPI). The leader (outer level) seeks to increase the cost of selected arcs, subject to a budget constraint. We propose a solution strategy that reformulates the problem as the interdiction of a Pareto-optimal set. This approach is embedded within an exact algorithm that decouples the interdiction model from the bi-objective shortest path problem. Our algorithm converges to the optimal solution while evaluating only a subset of the adversary's feasible paths. Computational experiments on two networks of different scales with randomly generated data demonstrate the method's efficiency. We also present a case study on human trafficking interdiction using real road network data from California, highlighting the approach's practical value even when the leader is only able to disrupt one of the adversary's objectives.

5 - Logistic Planning Under Vehicle Interdiction with No-Recourse

Abdulsamed Kagit, Georgia Institute of Technology, Atlanta, GA, United States, Mathieu Dahan, Oktay Gunluk

We study a logistic planning problem on an acyclic directed network where vehicles are subject to interdiction. In this problem, different types of commodities are supplied from a subset of nodes and demand nodes require specific amounts of these commodities. Each vehicle is dispatched from its origin node and has a fixed capacity. A unit cost is incurred for each unit of unmet demand at a demand node while no cost is incurred for excess supply.

The logistic planner first determines the vehicle routes, specifying through which arcs and by which vehicles the commodities are transported. After the logistics plan is established, the attacker selects an interdiction strategy that disables vehicles on the arcs they traverse. Interdicted vehicles are removed from the network along with the commodities they were carrying. Interdicting a vehicle on an arc incurs a cost and the attacker must remain within a given budget. In the no-recourse setting we consider, the logistic planner cannot revise the plan after interdictions are realized. Only the originally planned vehicle routes that remain intact can be used to deliver commodities. The logistic planner's objective is to minimize the total cost incurred from unmet demand in the worst-case scenario while the attacker's objective is to maximize it. We present a single level reformulation of this problem and develop a branch-cut-and-price algorithm to solve it.

Quantum Computing and Optimization

Invited Session

OPT: Linear and Conic Optimization

Chair: Pouya Sampourmahani, Lehigh University, Bethlehem, PA, United States

Co-Chair: Mohammadhossein Mohammadisiahroudi, Lehigh University, Hatfield, 19440, United States

1 - Quantum Computing Inspired Iterative Refinement for Semidefinite Optimization

Tamás Terlaky, Lehigh University, Bethlehem, PA, PA, United States, Mohammadhossein Mohammadisiahroudi, Pouya Sampourmahani, Zeguan Wu

Iterative Refinement (IR) is a classical computing technique for obtaining highly precise solutions to linear systems of equations, as well as linear optimization problems.

The limited precision of quantum solvers motivated us to develop the first IR scheme for solving semidefinite optimization (SDO) problems and explore two major impacts of the proposed IR scheme. First, we prove that the proposed IR scheme exhibits quadratic convergence of the optimality gap without any assumption on problem characteristics. As an application of our results, we show that using IR with Quantum Interior Point Methods (QIPMs) leads to exponential improvements in the worst-case overall running time of QIPMs, compared to previous best-performing QIPMs. We also discuss how the proposed IR scheme can be used with classical inexact SDO solvers, such as classical inexact IPMs with conjugate gradient methods.

2 - Almost-Exact Quantum Interior Point Method for Linear Optimization

Pouya Sampourmahani, Lehigh University, Bethlehem, PA, United States, Mohammadhossein Mohammadisiahroudi, Zeguan Wu, Jun-Kai You, Tamás Terlaky

The emergence of huge-scale, data-intensive linear optimization (LO) problems in applications such as machine learning has driven the need for more computationally efficient interior point methods (IPMs). While conventional IPMs are polynomial-time algorithms with rapid convergence, their per-iteration cost can be prohibitively high for dense large-scale LO problems. Quantum linear system solvers have shown potential in accelerating the solution of linear systems arising in IPMs.

In this work, we introduce a novel almost-exact quantum IPM, where the Newton system is constructed and solved on a quantum computer, while solution updates occur on a classical machine. Additionally, all matrix-vector products are performed on the quantum hardware. This hybrid quantum-classical framework achieves an optimal worst-case scaling of $O(n^2)$ for fully dense LO problems. To ensure high precision, despite the limited accuracy of quantum operations, we incorporate iterative refinement techniques both within and outside the proposed IPM iterations.

The proposed algorithm has a quantum complexity of $O(n^{1.5} \kappa_A \log(1/\epsilon))$ queries to QRAM and $O(n^2 \log(1/\epsilon))$ classical arithmetic operations. Our method outperforms the worst-case complexity of prior classical and quantum IPMs, offering a significant improvement in scalability and computational efficiency.

3 - Quantum-Inspired Hamiltonian Descent and Real-World Applications

Yuxiang Peng, Purdue University, West Lafayette, IN, United States, Jiaqi Leng, Samuel Kushnir, Jinglei Cheng, Pengyu Liu, Hanrui Wang, Xiaodi Wu

Quantum Hamiltonian Descent (QHD), a recent quantum algorithm, has been theoretically shown to achieve exponential speedups in certain optimization problems and has empirically outperformed state-of-the-art classical solvers on small-scale benchmarks. However, the limited scalability of current quantum hardware poses significant challenges for deploying QHD in real-world applications.

Motivated by the quantum and classical mechanics principles underpinning QHD, we introduce Quantum-Inspired Hamiltonian Descent (QIHD)—a scalable, classical variant that retains the core advantages of QHD while being suitable for large-scale optimization tasks. QIHD embeds optimization objectives into a classical Hamiltonian system derived from the dequantization of QHD's quantum dynamics, enabling more effective exploration of complex landscapes in large-scale and data-intense optimization problems compared to conventional methods.

In this talk, I will present the theoretical foundations of QIHD, its efficient GPU-based implementation, and its empirical performance across a range of benchmarks. I will also highlight real-world applications in various domains, where QIHD demonstrates better efficiency and higher solution quality compared to existing approaches. This work illustrates how quantum algorithms can inspire the development of modern optimization solvers with broader applicability.

4 - QAOA-GPT: Efficient Generation of Adaptive and Regular Quantum Approximate Optimization Algorithm Circuits

Ilya Safro, University of Delaware, Newark, DE, United States

We introduce QAOA-GPT, a generative framework that leverages Generative Pretrained Transformers (GPT) to directly synthesize quantum circuits for solving quadratic unconstrained binary optimization problems, and demonstrate it on the MaxCut problem on graphs. To diversify the training circuits and ensure their quality, we have generated a synthetic dataset using the adaptive QAOA approach, a method that incrementally builds and optimizes problem-specific circuits. The experiments conducted on a curated set of graph instances demonstrate that QAOA-GPT, generates high quality quantum circuits for new problem instances unseen in the training as well as successfully parametrizes QAOA. Our results show that using QAOA-GPT to generate quantum circuits will significantly decrease both the computational overhead of classical QAOA and adaptive approaches that often use gradient evaluation to generate the circuit and the classical optimization of the circuit parameters. Our work shows that generative AI could be a promising avenue to generate compact quantum circuits in a scalable way.

5 - An Exclusive-Sum-of-Products Pipeline for Grover Mixer Qaoa

Rebekah Herrman, University of Tennessee Knoxville, Knoxville, TN, United States, Matthew Brunet, Shilpi Shah, Mostafa Atallah, Anthony Wilkie

The Quantum Approximate Optimization Algorithm (QAOA) is a quantum algorithm used to approximately solve combinatorial optimization problems. Grover mixer QAOA (GM-QAOA) is a variant of the algorithm in which one can constrain QAOA to only search a feasible solution space instead of the space of all bit strings of length n . However, GM-QAOA requires a specialized initial state that depends on the feasible solution state. This initial state can be challenging to create on quantum hardware. In this work, we discuss an exclusive-sum-of-product approach for creating the GM-QAOA initial states and analyze the performance of the approach.

1 - Optimizing a Human-AI Warehouse: Integrating Product Stowage and Retrieval Using Autonomous Robots

Yun Fong Lim, Singapore Management University, Singapore, Singapore, Yuyu Liu, Marcus Ang, Kai Pan, Yugang Yu

We study an autonomous robotic system, such as a Kiva system, operating within a warehouse with multiple storage locations and multiple work stations over a multi-period horizon. Products arrive according to a predetermined schedule but their demands are uncertain. At the start of each period, we select pods from the warehouse to stow each arriving product at each station. Likewise, at the end of the period, we select pods to retrieve products that are demanded at each station. Our objective is to minimize the expected total travel cost of the pods. We formulate the integrated product stowage and retrieval problem over multiple periods with demand uncertainty as a stochastic optimization problem. To make the problem tractable, we partition the warehouse into several storage classes. We introduce a novel two-level hierarchical framework to solve the problem. In Level 1, we first choose classes to stow or retrieve products in each period. In Level 2, we select pods from the chosen classes to stow or retrieve the products in each period. This hierarchical framework scales effectively to large problem instances while yielding practical managerial insights. Numerical experiments suggest that our approach outperforms existing policies by about 49% on synthetic data and 26% on real data from an electronic equipment manufacturer. We find that when the warehouse has a sufficient number of storage classes, class assignment has a greater impact on performance than pod selection, and over partitioning the classes is unnecessary. However, pod selection becomes more critical when pod capacity is limited.

2 - Early Prediction of Product Success Through Integrating E-Commerce and Social Media Dynamics

Qili Wang, University of Florida, Gainesville, FL, United States, Yi Su, Liangfei Qiu, Hsing Kenneth Cheng

This study aims to predict product success to inform design and operational decisions during the early stages of product development. A key challenge at this stage lies in determining which features to include in a new product. Prior research in consumer behavior suggests that product performance is significantly influenced not only by individual features, but also by interactions among features and between features and the product itself. To model these complex relationships, we propose a graph-based data mining framework that integrates data from multiple word-of-mouth sources using text mining techniques. Our framework constructs a heterogeneous graph to capture product-to-product, product-to-feature, and feature-to-feature relationships. Experimental results show that our approach significantly outperforms existing benchmarks, demonstrating strong predictive capabilities and offering valuable practical implications for product development.

1 - Newborn Screening for Cystic Fibrosis

Ebru Bish, University of Alabama, Tuscaloosa, AL, United States

In this talk, I will present several projects on newborn screening (NBS) for cystic fibrosis (CF), a life-threatening genetic disorder. With over 1,000 known CF-causing variants, comprehensive genetic testing for CF NBS is both costly and capacity-limited. As a result, the U.S. screening protocol begins with a low-cost biochemical test measuring immunoreactive trypsinogen (IRT), which has limited efficacy. Only newborns with IRT levels above a set threshold proceed to genetic testing. I will introduce novel screening designs that can improve both the accuracy and efficiency of NBS. In addition to the practical implications of these designs, I will share insights into their real-world impact and outline ideas for future research inspired by this work.

2 - Operationalizing AI in Healthcare Delivery

Carri Chan, Columbia Business School, New York, NY, United States

The excitement about the potential of AI to improve healthcare delivery and lower costs continues to grow with ever increasing sophistication of data analytics tools. The healthcare industry has focused less on how to actually operationalize and make decisions based on their predictive models. This talk will discuss models, empirical evidence, and practical obstacles to overcome in order to achieve lower costs, better outcomes, and increased access to care.

1 - Proactive Admission Control for Emergency Departments: Integrating Demand and Inpatient Admission Delay Predictions

Jing Dong, Columbia University, New York, NY, United States, Ruicheng Ao, Xiaole (Alyssa) Liu, Martin Copenhaver

Emergency department crowding has severe consequences for patient outcomes and staff well-being. Addressing this challenge requires not only reactive measures but also proactive strategies that anticipate demand and admission delays. Advances in machine learning and predictive analytics now allow for more accurate forecasting of arrival rates, inpatient bed availability, and system bottlenecks, providing an opportunity to design data-driven interventions to enhance patient flow and mitigate crowding. In this work, we study how to integrate predictive demand and admission delay information into ED admission control decisions. By proactively regulating the acceptance of transfer patients based on real-time congestion levels and future system conditions, our approach provides a viable way to reduce delays and enhance overall efficiency in emergency care delivery.

2 - Generative AI in Clinical Documentation: Impact on Healthcare Efficiency and Provider Well-Being

Ragip Gurlek, Emory University, Atlanta, GA, United States, Diwas KC

This study empirically examines the effects of ambient documentation tools that automatically generate clinical notes from patient-provider conversations. Using panel data from a large hospital, we identify positive impacts on provider productivity and well-being. Results show these effects are moderated by contextual factors and provider characteristics.

3 - Place and Health: Built Environment and Healthcare Process Outcomes

Eric Xu, Mississippi State University, Mississippi State, MS, United States, RJ Niewoehner, Kevin Linderman

In recent years, the Center for Medicaid and Medicare Services has implemented a Hospital Readmissions Reduction Program to streamline processes and ensure quality outcomes. However, this reductionist approach to treatments has witnessed variable success in terms of patient outcomes. Therefore, we seek to understand the patient context in greater depth as to explain the variable outcomes in a group of patients with heart disease. This study uses patient data from the state of New York to understand how built environment contextual variables can impact treatment process outcomes.

4 - Operational Drivers of Nurse Turnover: Evidence from Operating Room Scheduling Data

Jaeyoung Kim, University of Dayton, Dayton, OH, United States, Ahmet Colak, Lawrence Fredendall

High turnover among operating room nurses poses critical challenges to care continuity and hospital performance. This study examines how the structure of work schedules influences nurse turnover in high-intensity care settings. Using granular hospital data and a pre-trained language model, we characterize nurses' work experiences in terms of their task and team assignments. We aim to quantify how scheduling patterns relate to nurse turnover, offering insights for improving workforce stability through data-informed management strategies.

1 - From Prediction to Policy - AI-Enabled Decision-Making in Fertility Treatment

Bogdana Jelic, University of Oxford, Oxford, United Kingdom, Agni Orfanoudaki, Holly Wiberg, Gurpreet Kalra

In recent years there has been rising concerns about fertility in the adult population worldwide. The World Health Organization estimates that 48.5 million to 186 million individuals may be infertile globally. In Vitro Fertilisation (IVF) procedure continues to represent one of the best treatments for parents waiting for a child, but it remains highly challenging in terms of financial cost, and difficulty to navigate through the complex decision making process, which is often emotionally and mentally overwhelming for the patients. Undergoing fertility treatments are known to be psychosocially demanding, at times with devastating consequences, including experience of loss, low self-esteem, and stigma. Approximately one-third of women and one-tenth of men with unresolved infertility get a psychiatric diagnosis, showing that the question of quick and more accessible fertility treatments is of essential importance. In recent years, there has been a rise in machine learning and AI models being leveraged in the IVF procedure, used for estimating various quantities of interest. But can it aid the patients, or can uncertainty in the models and induced incorrect estimates further impact patients' emotional difficulty? Our work aims to answer both questions. By using dynamic decision making processes we set up a framework for evaluating what is the optimal decision path for a patient, in terms of time-to-a-baby and cost sensitivity of a particular couple. At the same time, we discuss and establish uncertainty and error bounds for the misspecification of AI model estimations, and we establish the impact of such errors on patient-relevant measures.

2 - Biomarker-Guided Immunotherapy in Metastatic Melanoma

Jacob Jameson, Harvard University, Cambridge, MA, United States

PURPOSE: The treatment landscape for metastatic melanoma has been transformed by immunotherapy, with two primary first-line options: PD-1 inhibitor monotherapy or combination PD-1/CTLA-4 blockade. While combination therapy (nivolumab+ipilimumab) shows improved response rates compared to PD-1 monotherapy, it substantially increases both toxicity and costs. However, a subset of patients demonstrates intrinsic resistance to PD-1 monotherapy, experiencing early progression and poor outcomes. Here, we quantify the health economic value of implementing this biomarker-guided immunotherapy selection strategy.

METHODS: Building on the validated modified decision tree (MDT) model from Tarantino et al. that uses tumor genomic heterogeneity and ploidy to predict intrinsic resistance to PD-1 monotherapy, we developed a partitioned survival model calibrated to 10-year data from CheckMate-067. The model incorporates three health states (progression-free, progressed, dead) with parametric spline functions fit to overall survival and progression-free survival data to evaluate the impact of biomarker-guided therapy selection.

RESULTS: The MDT model shows that patients predicted to be resistant to PD-1 monotherapy have significantly worse survival on monotherapy, but notably, 43% responded to combination therapy, suggesting substantial clinical benefit from appropriate treatment selection. Our survival modeling demonstrates that biomarker-guided therapy selection can improve quality-adjusted survival by directing resistant patients to combination therapy while sparing responsive patients from unnecessary toxicity. Preliminary economic analyses suggest favorable cost-effectiveness of this precision medicine approach compared to standard unguided treatment selection.

CONCLUSIONS: Implementation of this genomic biomarker-guided approach to immunotherapy selection shows promise for optimizing clinical outcomes in metastatic melanoma by matching patients to the most appropriate first-line therapy.

3 - Prediction of Response to Intra-Articular Injections of Hyaluronic Acid for Knee Osteoarthritis

Eva Lee, The Data and Analytics Innovation Institute, Atlanta, GA, United States

Osteoarthritis (OA) is a degenerative joint disease, most commonly affecting the knee. About half of knee OA patients ultimately undergo surgery, though many procedures may be avoidable. Intra-articular injections of hyaluronic acid (HA) offer a non-invasive, cost-effective alternative that improves knee function, yet treatment efficacy remains debated. Outcomes often depend on patient characteristics such as age, weight, gender, and OA severity, as well as injection site and placement.

This study employs a multi-stage, multi-group machine learning model to identify features that predict patient response to various HA treatments. The algorithm uncovers subgroups of patients most likely to benefit from HA therapy. Baseline results highlight factors such as weight, smoking status, and smoking frequency as key predictors, enabling accurate identification of patients best suited for HA injections. The model achieves over 89% blind prediction accuracy.

These findings support more selective administration of HA, improving therapy success rates while reducing unnecessary procedures. Predicted response information can also be shared with patients to align treatment with their values and preferences. Additionally, decision-support tools derived from the model allow physicians to monitor whether patients are meeting expected response levels and, if not, to consider corrective action.

To our knowledge, this represents the first machine learning approach to predicting responses to HA injections for knee OA. The framework is generalizable and may be extended to guide treatment decisions for other conditions.

AI-Driven Decision Analysis: Towards Human and Skills Optimization in the Digital Era

Invited Session

Decision Analysis Society

Chair: Irad Ben Gal, Tel Aviv University, TEL AVIV, Israel

Co-Chair: Hila Chalutz-Ben Gal, Bar-Ilan University, Ramat Gan, Israel

1 - Social Federated Learning (Sfl):: New Insights and Examples**Irad Ben-Gal, Tel Aviv University, Tel Aviv, Israel**

Federated Learning offers a framework for collaborative model training without sharing raw data, thereby addressing critical privacy and communication costs overcoming challenges in distributed environments. This research introduces a novel data sharing scheme that leverages Social Federated Learning (SFL) to enhance performance in non-industry settings. Examples include: Healthcare, Cyber security, and industrial IoT. Empirical evaluations, using synthetic and real-world datasets, demonstrate that our scheme preserves high levels of model accuracy of centralized baselines, while providing strong guarantees on interpretability and privacy.

2 - Social Media Impact and Smartwatch Monitoring: Prevalence and Early Markers of Ptsd and Anxiety Following Mass Traumatic Events**Erez Shmueli, Tel-Aviv University, Tel-Aviv, Israel, Dan Yamin**

We investigated PTSD, anxiety, and stress in individuals indirectly exposed to the October 7 events in Israel. Our study utilized data from a three-year prospective study of 4,806 smartwatch users who completed daily questionnaires, and a panel study surveying 2,536 individuals twice. Stress symptoms were measured daily, while PCL-5 and GAD-7 questionnaires assessed PTSD and anxiety prevalence. After October 7, stress levels soared, with PTSD prevalence reaching 22.9-36.0% at 7-8 weeks post-event, and remaining exceptionally high at 15.9-24.7% after 7 months. We found a strong correlation between increased PTSD risk and extensive media consumption. Smartwatch data revealed early PTSD markers such as pronounced increases in stress levels and declines in mood, physical activity, and sleep quality within the first week. This study underscores the significant impact of media exposure on PTSD development and the value of continuous physiological monitoring for early detection of PTSD after mass traumatic events.

3 - Advancing Machine Learning-Based Job Recommender Systems: Human Skills-Based Approach**Hila Chalutz-Ben Gal, Bar-Ilan University, Ramat Gan, Israel**

In recent years the widespread adoption of machine learning-based job recommender systems became a major component in predictive human resources analytics. However, recent workforce disruptions such as freelancing, gig, and flexible work have resulted in the emerging need to adopt new models and tools to support and implement state-of-the-art job recommender systems. To address contemporary workforce disruptions, we utilize the Person-Skill Fit framework to present a robust analysis of the machine learning based job recommender systems literature. We adopt a scoping review method to systematically analyze seventy-three papers based on predetermined inclusion and exclusion criteria. Our results indicate that job recommender systems may benefit from a skill-based approach and should therefore be adopted to address new workforce challenges. The research main contribution is a decision support tool for implementing machine learning-based job recommender systems and upskilling for improved human capital management. KEYWORDS: Job Recommender Systems; Human Resources Analytics; Machine Learning; Iterative Scoping Review.

4 - Continuous Monitoring and Early Detection of Health and Well-Being Conditions Using Smartwatches: a Systematic Review of AI Advances**Liora Shmueli, Bar-Ilan University, Tel Aviv, Israel, Maya Reiner, Erez Shmueli**

This systematic review investigates the role of smartwatches in the continuous monitoring and early detection of health and well-being conditions, with a focus on recent advances in artificial intelligence (AI). Continuous monitoring technologies are gaining prominence as they offer the potential for early diagnosis and timely intervention, especially when combined with machine learning and deep learning techniques. As off-the-shelf smartwatches become increasingly popular beyond fitness tracking, their integration into healthcare contexts has expanded considerably over the last few years.

This review follows the PRISMA guidelines and based on the Cochrane Handbook for Systematic Reviews of Interventions. A comprehensive search was conducted in early 2025 across PubMed, Scopus, and IEEE databases. The review covers peer-reviewed studies published between 2014 and 2024. Studies were eligible if they provided quantitative evidence

on the accuracy or clinical utility of biometric data collected via commercially available smartwatches, combined with machine learning and deep learning techniques. Over 6,000 articles were screened, resulting in a final sample of studies that met rigorous inclusion criteria.

Our findings emphasize the positioning of AI-enhanced smartwatches as key instruments in monitoring and detecting health and well-being conditions, as well as offering predictive insights that can improve patient outcomes and support personalized healthcare.

5 - Exploring the Potential of Large Language Models for Vestibular Rehabilitation Education: a Comparative Evaluation of ChatGPT, Google Gemini, and Clinicians**Yael Arbel, Bar-Ilan University, Ramat-Gan, Israel, Yoav Gimmon, Liora Shmueli**

This study aimed to compare the performance of two large language models, ChatGPT and Google Gemini, against experienced physical therapists and students in responding to multiple-choice questions related to vestibular rehabilitation (VR). The study further aimed to assess the accuracy of ChatGPT's responses by board-certified otoneurologists.

Thirty physical therapist professionals experienced with VR and Thirty physical therapy students completed a 20-item multiple-choice questions Vestibular Knowledge Test (VKT), divided into three categories: Clinical Knowledge, Basic Clinical Practice, and Clinical Reasoning. ChatGPT and Gemini were given the same test. Three board-certified otoneurologists independently evaluated the accuracy of each response using a 4-level scale, ranging from comprehensive to completely incorrect.

ChatGPT3.5 outperformed Google Gemini with a 70% score on the VKT test, while Gemini scored 60%. Both excelled in Clinical Knowledge scoring 100% but struggled in Clinical Reasoning (ChatGPT: 50%, Gemini: 25%). According to three otoneurologic experts, ChatGPT's accuracy was considered "comprehensive" in 45% of VKT, while 25% were found to be completely incorrect. ChatGPT provided "comprehensive" responses in 50% of Clinical Knowledge and Basic Clinical Practice questions, but only 25% in Clinical Reasoning. To examine model improvements, updated versions of both LLMs were also evaluated on the same test; results are under analysis and will be presented.

Findings highlight that while LLMs show promise in factual knowledge, their clinical reasoning remains limited. Use of LLMs in clinical education should be approached cautiously, with careful question formulation and expert validation. Integrating LLMs with clinical expertise and guidelines may enhance learning while mitigating risks

6 - A Bi-Level Optimization Decision Support Tool for Maximizing Company Profit Through Employee Retention**Iris Forma, Tel-Aviv Afeka Academic College of Engineering, School of Industrial Engineering and Management, Tel Aviv - Yafo, Israel, Inbal Singer, Gonen Singer, Hila Chalutz Ben-Gal**

The rise of flexible work greatly impacts how firms manage and retain employees. This research introduces two bi-level mathematical models to help companies improve workforce retention by integrating flexibility and attractive benefits. The upper level focuses on maximizing firm profit, while the lower level aims to minimize the gap between desired salary and total benefits for employees. Model I assumes fixed salaries for each work plan and job type, whereas Model II allows for fully flexible salary determination. Both models provide exact solutions using a mixed-integer formulation. Experimental analysis shows that in some scenarios, Model II leads to significantly

higher firm profit than Model I. However, when work plan flexibility is similar across markets and firms, the profit difference is minimal. These results highlight the practical relevance of our solutions. This study makes three important contributions. First, from a methodological perspective, it introduces a novel bi-level modeling approach that can proactively enhance employee retention and, consequently, decrease employee turnover. Second, from a practical perspective, it offers concrete solutions to new workforce challenges by providing a decision support tool capable of optimizing employee retention through the creation of customizable and flexible work plans and salaries, specifically designed to meet diverse employee needs while simultaneously maximizing the company's profit. Third, the study highlights the critical importance of incorporating managerial insight into the model's parameters and effectively utilizing experimental analysis as a vital decision support mechanism to achieve optimal firm profitability.

1 - The Effect of Corporate Participation on Volunteer Contributions in Online Communities

Eunae Yoo, Indiana University, Bloomington, IN, United States, Yuqing (Aric) Cheng, Abhishek Nagaraj, Elliot Rabinovich

Online communities often rely on volunteer contributions to generate content, but increasingly attract direct corporate participation as they mature. We examine how corporate contributions affect volunteer engagement in these platforms, addressing a gap in the literature where existing theories offer conflicting predictions. Using OpenStreetMap data from Brazil (2017-2022), we employ an event study methodology to analyze volunteer mapping activities before and after corporate entry across different regions. Our findings reveal that corporate participation significantly increases volunteer contributions rather than crowding them out. This positive effect is particularly pronounced when corporate contributors engage broadly with the platform rather than focusing narrowly on certain regions. We find that such corporate involvement motivates dedicated volunteers to not only contribute more but also redirect their efforts toward previously neglected and less mature areas of the map. These results suggest that strategic corporate participation can enhance overall platform quality by complementing volunteer efforts. Our work contributes to understanding the complex dynamics between different contributor types in online communities and offers insights for platform governance that effectively balances volunteer and corporate participation.

2 - Analyzing Social Media Discourse on Child Protective Services to Enhance Timely Support

Yanhan (Savannah) Tang, SMU Cox School of Business, Dallas, TX, United States

The rise and popularity of social media platforms like Reddit have created a valuable opportunity to study public discourse around child protective services (CPS). This project leverages large language models to analyze Reddit posts and comments related to CPS, assess sentiment-topic alignment, and identify post characteristics associated with receiving timely support. Based on these results and insights, we offer recommendations to help users improve the quality and effectiveness of their posts so that they are more likely to receive timely and helpful responses from the community.

3 - Theory-Guided Representational Richness for LLM-Based Assessment

Xinyuan Zhang, UNIVERSITY OF NOTRE DAME, SOUTH BEND, IN, United States, Junhui Cai, Ahmed Abbasi

With the current rapid development in generative AI, pretrained models, including Large Language Models (LLMs), are increasingly being for assisting humans in evaluating both human and generative outputs. This increasing LLM usage presents several opportunities for improving and expanding on current NLP studies. LLMs are capable of grasping richer information across a large lexicon domain, and among large volume inputs. However, further processing the multi-dimensional and large-scale information from LLMs can be computationally challenging, while over-simplified techniques fail to pertain granular and valuable signals. We propose a theory-guided framework that creates parsimonious representations of multi-dimensional information from LLM-based assessments with downstream impact. We use tensor-based representations and extract meaningful patterns, that effectively address interplay between tokens and parallel representations for text. We compare our representations with state of the art methods, and demonstrate downstream values in various practical tasks through case studies across several testbeds.

4 - Can AI-Generated Stories Heal the Heart?

Jiayi Xu, The University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, Yifan Yu, Wendao Xue, Junyu Yao, Qiaoxiang Hu

Stories are central to how people understand the world and themselves. In mental health, stories are known to support healing. Immersion in resonant stories encourages emotional processing, perspective-taking, and self-reflection, while reducing psychological resistance to new insights. However, stories created by humans are limited and people may not always have access to high-quality and personally relevant stories. The rise of generative AI (GenAI) offers new possibilities: by rapidly producing tailored, empathetic stories, GenAI enables people to engage with and benefit from stories that feel personally meaningful. This study aims to understand a novel conversational healing mode in which people converse with a chatbot based on personalized, GenAI-generated stories. We will conduct an experiment to understand two fundamental questions: (1) Is this story-based healing effective? (2) How do people benefit from this healing mode? Our research expects to contribute empirical evidence on the healing potential of GenAI-powered storytelling and to uncover the behavioral mechanisms that underlie its impact.

5 - Optimizing the Ineffable: Generative Policy Learning for Human-Centered Decision-Making

Zekai Fan, Carnegie Mellon University, Pittsburgh, PA, United States, Michael Lingzhi Li, Shixiang (Woody) Zhu

Algorithmic decision-making is widely adopted in high-stakes applications affecting our daily lives but often requires human decision-makers to exercise their discretion within the process to ensure alignment. Explicitly modeling human values and preferences is challenging when tacit knowledge is difficult to formalize, as Michael Polanyi observed, "We can know more than we can tell." To address this challenge, we propose generative near-optimal policy learning (GenNOP). Our framework leverages a conditional generative model to reliably produce diverse, near-optimal, and potentially high-dimensional stochastic policies. Our approach involves a re-weighting scheme for training generative models according to the estimated probability that each training sample is near-optimal. Under our framework, decision-making algorithms focus on a primary, measurable objective, while human decision-makers apply their tacit knowledge to evaluate the generated decisions, rather than developing explicit specifications for the ineffable, human-centered objective. Through extensive synthetic and real-world experiments, we demonstrate the effectiveness of our method.

Entrepreneurial and Analytics Path for Decisions: Policy, Energy, Water, and Innovations

Invited Session

Decision Analysis Society

Chair: Christian Hernandez-Negron, California State University, Amherst, United States

1 - Discrete Event Simulation for Nuclear Waste Disposition

Veronica White, FAMU-FSU College of Engineering, Tallahassee, FL, United States, Alexis Andaverde, Hiram Moya

Nuclear waste disposal is a growing issue, with significant backlogs of nuclear waste at many national laboratories and research centers dealing in medical research, clean energy, and other nuclear activities. This backlog prevents future use of nuclear materials, risks environmental impacts, and complicates federal and state regulatory

compliance, making disposal costly. Rising interest in nuclear energy will further inflate the issues of backlogged nuclear waste. Therefore, effectively managing and disposing of nuclear waste is critical to invest in future nuclear solutions. Simulation approaches can provide insight into effective resource allocation and waste processing operations to stabilize productivity and cut the backlog of nuclear waste. Therefore, we created a discrete event simulation in ExtendSim to model a nuclear waste disposition process, which is a process within nuclear waste disposal. We inform the simulation by evaluating a case study of the Savannah River National Laboratory (SRNL), which is a United States nuclear waste disposal facility, using data and insights from SRNL staff.

2 - Watts and Drops: Renewable-Aware Co-Optimization of Power and Water in Desalination Plants

Ahmed Alahmed, King Fahd University of Petroleum and Minerals, Dharhan, Saudi Arabia, Audun Botterud, Saurabh Amin

As water and energy systems become increasingly interdependent, there is a growing need for integrated optimization frameworks that enable cost-effective and grid-responsive operation of critical infrastructure such as water desalination plants (WDP). We develop a mathematical framework to co-optimize water and electricity scheduling in a profit-maximizing WDP that operates both thermal- and membrane-based technologies. The price-taking WDP sells desalinated water to a water utility at a given price and engages in bi-directional electricity transactions with the grid, purchasing or exporting power based on its net electricity demand. We show that the optimal scheduling policy depends on the plant's internal renewable generation and follows a simple threshold structure. Under the optimal policy, thermal-based water output decreases monotonically with renewable availability, while membrane-based output increases monotonically. We characterize the structure and intuition behind the threshold policy and examine key special properties.

3 - Modelling to Generate Continuous Alternatives: Enabling Real-TIME Feasible Portfolio Generation in Convex Planning Models

Michael Lau, Princeton University ZERO Lab, Princeton, NJ, United States, Neha Patankar, Jesse Jenkins

Modelling to Generate Alternatives (MGA) provides an optimization method for capturing many near-cost-optimal system configurations, and can provide insights into the tradeoffs between objectives and flexibility available in the system. However, MGA is currently limited in interactive applicability to these problems due to a lack of methods for allowing users to explore near-optimal feasible spaces. In this work we describe Modelling to Generate Continuous Alternatives (MGCA), a novel post-processing algorithm for convex planning problems which enables users to rapidly generate new interior solutions, incorporate new constraints, and solve within the space with convex objectives. MGCA begins with a dimensionality reduction to capacity decisions and metric values. We then take advantage of convex combinations to generate interior points by allowing user weight specification and encoding convex combinations in an optimization problem with user-defined additional constraints and objective. Dimensionality reduction enables this problem to solve in tenths of a second, suitable for analysis in interactive settings. We discuss the interpolation of capacity and operational metric values, finding capacity metrics can be perfectly interpolated while operational metrics remain within the feasible range of the points used to create them. We demonstrate interpolated solutions can be exported and re-solved with an economic dispatch model to provide operational metric values consistent with least-cost decision-making and show interpolated metric values are generally within 10% of the optimal value.

4 - Multi-Vector Optimization Framework to Support Equitable Building Decarbonization in Urban Environments

Jun Wen Law, Massachusetts Institute of Technology, Cambridge, MA, United States, Dharik Mallapragada

Regional building decarbonization efforts in cold climates emphasize electrification coupled with expansion of low-carbon electricity supply. This transition requires substantial investments across the entire electricity supply chain—generation, transmission, distribution, and end-use—while also addressing the role of existing natural gas infrastructure currently serving both building and power sectors. This study presents a mixed-integer optimization framework for joint electricity and natural gas infrastructure planning to support building decarbonization. Unlike prior studies that generally emphasize bulk energy infrastructure aspects of this problem, our approach spans both transmission and distribution networks, offering a comprehensive evaluation of the system impacts of alternative building decarbonization strategies. The model evaluates the least-cost investment and operation of the integrated energy system to meet heating and non-heating demands, while accounting for: a) temporal and spatial variability in demand, b) network operations, c) end-use technology adoption, d) policy drivers such as emissions targets and distributional equity, and e) a wide range of low-carbon technologies including clean generation, storage, low-carbon fuels, and district heating. The value of the framework is demonstrated by evaluating a case study developed using data from New York City. Preliminary results evaluating alternative pathways to achieve mid-century decarbonization targets show that hybrid pathways—such as electrification with low-carbon fuels—as opposed to full electrification can reduce the urgency for rapid electrification, preserve existing infrastructure, and prevent premature asset retirements and costly upgrades. The study also highlights the value of coordinated investment planning across both bulk and distribution energy systems to support cost-effective and equitable decarbonization.

1 - Optimizing HVAC Control for Energy Efficiency and Occupants' Health and Productivity

Ziwei Liu, University of Tennessee, Knoxville, TN, United States, Mingzhou Jin, Zhihong Pang

Buildings significantly contribute to global energy consumption, with Heating, Ventilation, and Air Conditioning (HVAC) systems accounting for approximately 38% of commercial building energy usage. As people spend roughly 90% of their time indoors, maintaining optimal Indoor Environmental Quality (IEQ), including thermal comfort, volatile organic compound (VOC) levels, and CO₂ concentration, is critical for occupants' health and productivity. Thus, balancing energy efficiency and IEQ constitutes a core optimization challenge in HVAC control in buildings.

This paper develops a physics-based optimization model integrating thermal dynamics, indoor air quality, pollutant dispersion, and HVAC energy consumption. To handle inherent nonlinearity and nonconvexity, this study introduces a solution-oriented piecewise McCormick relaxation for bilinear terms, along with a feasibility adjustment algorithm to ensure the relaxed formulation yields a feasible solution to the original constraints. Four methods (Baseline, Gurobi, Partial Approximation, and Full Approximation) are benchmarked over 48 scenarios involving varying temperatures and outdoor air pollution levels, each scenario executed over 10 instances. Performance metrics include average CPU time, solution deviations, and statistical significance (P-values). Results illustrate critical trade-offs among energy efficiency, feasibility, and computational cost. Specifically, the Full Approximation approach achieves superior energy efficiency at high computational cost, whereas Baseline, while faster, frequently yields infeasible solutions.

Ultimately, our proposed optimization framework provides a comprehensive and practically implementable strategy for improving building sustainability and energy efficiency without compromising indoor environmental quality for occupants' health and productivity. In addition, the benchmarking analysis provides quantitative guidance for selecting solution methods that best balance energy savings, feasibility, and computational burden.

2 - On Solution Structure and Stability of Optimality-Based Clustering

Soroush Akbarijokar, University of Pittsburgh, Pittsburgh, PA, United States, Taewoo Lee

We develop a new clustering problem where data points represent decisions made by solving (partially known) optimization problems and are clustered based on their latent decision-making preferences, which we term the optimality-based clustering problem. While the problem is first modeled as a large-scale mixed-integer program, we elucidate its connection to facility location problems, which we exploit to derive a more efficient reformulation. We further propose a stability-driven variant of the problem to mitigate the impact of data noise and uncertainty on the clustering solution. We discuss practical implications of this framework in healthcare applications including eliciting group diet preferences and clustering clinical pathways based on underlying clinical preferences.

3 - Facility Layout Adaptation Optimization: a Matheuristic Approach

Mingze Li, Georgia Institute of Technology, Atlanta, GA, United States, Jihye Jung, Benoit Montreuil

This study introduces a novel Facility Layout Problem variant, FLP with Base Layouts (FLP-BL), addressing the challenge of automating the design of consistent industrial layouts across multiple facilities. Current industry practice relies heavily on manual, heuristic-based design, especially for complex layouts with integrated material handling networks. In fast-evolving, geographically distributed industries, typical of today's market, companies may operate multiple facilities in different locations that share identical set of resources. Each new facility requires a distinct layout that fits the new building while maintaining consistency across locations to enhance operational familiarity, an aspect previously overlooked in academic research. We propose a three-stage mixed-integer programming (MIP) based matheuristic model to automate facility layout design. The objective is to minimize material handling flow cost while preserving the core structure of expert-designed base layouts. Constraints ensure stations are within building boundaries, non-overlapping, and do not overlap with aisles, while maintaining aisle network connectivity for material handling origin and destination pairs. A real-world case study demonstrates that our model achieves lower flow costs within one-third of computational time compared to directly solving the base MIP model for 24 hours. Furthermore, we show that with minor changes, our matheuristic model can also be used to solve the general FLP from scratch. This research offers a practical and efficient approach to automated facility layout design for modern industrial needs.

4 - Qualitative-Metric Clustering: Minimal Clique Cover with Minimal Edge-Cuts

Yuxuan Ren, Georgia Tech, Atlanta, GA, United States, Shijie Deng

This study presents a qualitative-metric clustering framework that concurrently balances three objectives—high within-cluster cohesion, low between-cluster similarity, and a parsimonious number of clusters. We tackle the ensuing combinatorial problem with a branch-and-price scheme: the restricted master problem is modeled as a weighted set-covering formulation, and the pricing sub-problem is expressed as a maximum-weight clique search. A destroy-and-repair heuristic is embedded in the pricing step to generate high-quality columns early in the search. The methodology is validated on Financial Transmission Rights (FTR) trading data, where profitable FTR paths are identified by clustering on Shift Factor (SF) matrix, demonstrating both its practical relevance and its effectiveness.

5 - Decision Support for Integrating Remanufacturing and Recycling Facilities into Manufacturing Plants Under Sourcing Cost Uncertainties and Product Lifecycle Considerations

Mohammad Ahnaf Sadat, Iowa State University, Ames, IA, United States

In this study, we examine the strategic decision-making involved in integrating remanufacturing and recycling facilities into existing manufacturing plants, using turbine blade production for gas turbines as a representative case study. Our analysis emphasizes uncertainties associated with sourcing costs, particularly manufacturing and remanufacturing expenses, which are modeled as stochastic dynamic variables. Additionally, the analysis accounts for variations in product demand throughout the product lifecycle and treats the returned products' quality during remanufacturing as deterministic dynamic variables. To quantify the benefits of investment flexibility, we employ Real Options Analysis, utilizing Monte Carlo simulations. Our objectives include identifying optimal conditions for facility integration, determining the strategic value derived from investment flexibility under uncertain economic conditions, and investigating how key factors, such as cost variabilities, product lifecycle dynamics, and the quality of returned items, impact the overall decision-making process.

6 - Optimal Hurricane Evacuation Routing with Private and Public Vehicles: a Joint Chance-Constrained Stochastic Programming Model

Michael Geisecke, University of Missouri, Columbia, MO, United States, Hyeon Suk Na, James Noble

Efficient evacuation planning is crucial for mitigating the adverse effects of major hurricanes, especially in urban areas where a substantial portion of the population relies on public transportation on a daily basis. The evaluation of evacuations from major hurricanes such as Hurricane Idalia, Ian, and Barry has revealed critical gaps in evacuation planning, with inadequate public transportation contributing to loss of life. However, the role of public transportation remains underrepresented in existing hurricane evacuation studies. To address this gap, we develop a stochastic programming model that integrates the cell transmission model with chance constraints, which provides a robust framework for capturing uncertainties in road capacity and assessing their impact on the evacuation of public vehicles. The objective of the proposed joint chance-constrained programming (JCCP) model is to support emergency management decision-making by minimizing the total cumulative time that evacuees spend within the evacuation transportation network. We reformulate the JCCP model using the sample average approximation method, which employs Monte Carlo simulations to approximate the distributions of uncertain parameters. This reformulation results in a mixed-integer linear programming model, offering a more computationally efficient alternative to solving the original stochastic optimization problem. The applicability of the proposed model is validated through a case study focused on the Miami metropolitan area in Florida. The experimental results confirm our model's effectiveness in generating optimal evacuation routes across various hurricane scenarios. Additionally, our model estimates the minimum number of buses required for evacuations and evaluates alternative bus routing policies to reduce traffic congestion during evacuations.

Disinformation and Impact on Infrastructure Systems

Invited Session

Decision Analysis Society

Chair: Kash Barker, University of Oklahoma, Norman, OK, United States

1 - Modeling the Impact of Disinformation on Infrastructure Networks with Causal Failures Across Interconnected Layers

Alice Nanyanzi, University of Oklahoma, Norman, OK, United States, Kash Barker, Sridhar Radhakrishnan

The widespread dissemination of disinformation poses a serious threat to society, especially when used to disrupt the performance of critical networks. We model this threat using a two-layer network consisting of an information layer (A), where dis/information spreads, and a physical layer (B), where the physical network operates. For example, false messages about electricity rate hikes in layer A can alter consumer behavior, increase demand, and potentially overload power lines, leading to blackouts in layer B. These disruptions reveal how vulnerabilities in one layer can propagate to another. To capture the dynamics of disinformation spread in layer A, we develop an adaptive influence model that reflects how decision-making and heterogeneous susceptibility evolve during disinformation campaigns. To examine the interdependencies between layers, we present a novel approach that focuses on direct cause-and-effect relationships, where the likelihood that a node in A causes a path failure in B is governed by stochastic processes. We study this by formulating it as problem that determines the minimum number of stochastic causal failures in A required to significantly disrupt the ability of B to meet demand or in the worst case cause widespread service interruptions in B. Illustrating with data from social media and power grid networks, we demonstrate how disinformation in layer A can activate causal pathways that result in stochastic failures in infrastructure layer B. This framework provides insight into the cascading risks that arise from the interaction between information and physical systems.

2 - Interdicting Disinformation Spread to Mitigate Impacts on Public Transit Networks

Daniel Cabrera, University of Oklahoma, Norman, OK, United States, Andrés Gonzalez, Kash Barker

The growing influence of online information has increased the exposure of critical infrastructure systems to the risks of disinformation. This study examines how false messages about transit station closures can disrupt public transportation systems by altering user behavior. We propose a two-layer modeling framework that captures both the spread of disinformation and its impact on transit operations. The information layer models user susceptibility based on personality traits and simulates message propagation through an information diffusion process. The physical layer represents the transit network as a multi-commodity flow model, capturing user movement under different information awareness scenarios. These layers are integrated to assess how disinformation alters traffic patterns and degrades system performance. We apply this framework to a case study of the New York City subway system. Our results demonstrate that disinformation can significantly increase travel times and system congestion. However, targeted protection strategies—such as informing a small, strategically chosen subset of users—can mitigate these effects and improve resilience. This work highlights the importance of incorporating behavioral and network dynamics into infrastructure protection models. It provides a novel operational research approach to evaluate and counter the systemic risks posed by disinformation.

3 - Understanding the Role of Emotion in the Spread and Impact of Disinformation

Elena Bessarabova, University of Oklahoma, NORMAN, OK, United States, Matthew Weber, Casey Randazzo

Understanding the role of emotion in the spread and impact of disinformation is essential. Emotions such as fear, anger, and anxiety can override rational judgment and decision making, making individuals more susceptible to disinformation and conspiratorial content. Disinformation often strategically leverages these emotions to generate urgency, foster distrust in institutions, and motivate maladaptive decision-making such as the rejection of public health measures. Disinformation does not merely disseminate falsehoods—it deliberately targets emotional vulnerabilities to enhance engagement. Emotionally charged content spreads more rapidly, leaves stronger cognitive impressions, and can distort memory and perceived credibility through mechanisms such as the availability heuristic. In the case of conspiratorial ideation, once individuals become emotionally invested in conspiracy theories, they exhibit greater resistance to corrective information, underscoring the need for early intervention. This presentation will discuss recent empirical findings on the role of emotions such as fear in disinformation processing, including its influence on disinformation spread and resistance to conspiratorial beliefs. We also discuss intervention strategies that aim to reduce emotional susceptibility to disinformation, particularly in crisis contexts where emotional vulnerability is heightened. These findings have important implications for designing more effective counter-disinformation efforts and public communication strategies.

4 - Modeling Disinformation as Wave Dynamics: a Quantum Graph Framework for Belief Evolution

Sridhar Radhakrishnan, University of Oklahoma, Norman, OK, United States, Kash Barker

Disinformation does not spread as a simple contagion but rather evolves as a complex, continuous process shaped by repeated exposure, reinforcement, and local social network structure. Classical models based on epidemic dynamics fall short in capturing this complexity, as they rely on discrete state transitions (e.g., susceptible, infected, recovered) that assume binary belief states. To address such limitations, we introduce a novel modeling framework based on quantum graphs, which naturally encode belief as a continuous, dynamic process akin to wave propagation. We begin with an information graph (IG), where nodes represent individuals and edges represent influence links. From this, we construct a quantum graph (QG) as the incidence graph of IG, where each node in QG corresponds to an edge in IG, and each edge in QG connects QG nodes that share a common IG node. In this formulation, the wave function defined on each edge of QG models the evolving belief state of a node in IG, capturing how individuals gradually adopt, resist, or amplify disinformation based on their interactions. We model belief evolution using wave functions governed by time-dependent partial differential equations, such as the Schrödinger or wave equation. These wave functions enable the modeling of continuous and temporally sensitive belief change, including interference from multiple sources, reinforcement through repetition, and attenuation due to skepticism or conflicting signals. The core strength of this quantum graph framework lies in the ability to encode belief dynamics through the deliberate design of wave functions and boundary conditions.

Sustainability and Resilience in Supply Chains

Invited Session

MSOM: Supply Chain

Chair: Shi Chen, University of Washington Foster School of Business, Seattle, WA, United States

Co-Chair: Xiaoxuan Hou, University of Washington, Seattle, WA, United States

1 - Greenwashing Under Competition

Soraya Fatehi, The University of Texas at Dallas, Richardson, TX, United States, Anyan Qi, Liqun Wei, Jianxiong Zhang

Growing consumer awareness of corporate social responsibility (CSR) has motivated firms to invest in CSR initiatives to gain a competitive edge. However, a phenomenon known as greenwashing has emerged, whereby firms exploit observable CSR activities and advertising solely as a marketing tactic. We develop a game-theoretic model with two types of firms: a socially responsible firm that intrinsically values CSR and a profit-maximizing firm that may greenwash. Firms can invest in observable and/or unobservable CSR activities as well as CSR advertising. Consumers are socially minded but face limited information about the firms' actual CSR type, inferring the type through observable CSR investment and advertising. We examine how the advertising influence and competition intensity affect equilibrium strategies and social welfare. Our findings show that when advertising influence is high, the profit-maximizing firm engages in greenwashing; when it is moderate, the socially responsible firm overinvests in CSR to deter imitation; and when it is low, the two firm types naturally separate. Notably, under high transparency, stronger advertising influence can increase both overall CSR activity and social welfare. Moreover, when transparency is low, the profit-maximizing firm strongly prefers greenwashing; in such settings, if competition intensity is low, greenwashing persists, whereas if competition intensity is high, the socially responsible firm responds by over-investing to prevent greenwashing. Greenwashing produces both negative and positive outcomes. Although it erodes consumer surplus, it can spur higher CSR activity in a competitive environment, enhancing social welfare.

2 - Collective Renewable Power Purchase Agreement: Negotiation and Risk-Sharing Mechanisms

Xiaoxuan Hou, University of Washington, Seattle, WA, United States, Shi Chen

Background: Over 400 companies spanning more than 175 markets worldwide have committed to using 100% renewable electricity. But achieving these goals can be challenging. In the past decade, long-term power purchase agreement (PPA) has gained popularity among large corporations like Google and Amazon (buyers) as the main vehicle to source supply from renewable energy developers (sellers). Under a PPA, the buyer commits to purchasing renewable energy from the seller at a contract price for a predetermined length of time. Yet signing a PPA remains difficult for small-to-medium-sized corporate buyers, who may not have the expertise or lack sufficient negotiation power on their own. As a result, collective PPAs have emerged as a potential solution.

Method: We compare the performance of three widely used negotiation mechanisms for buyers to sign PPA contracts: separate negotiation, agent-based negotiation, and joint negotiation. For each mechanism, we devise a two-stage problem involving Nash-bargaining based negotiation, followed by post-contract operational optimization.

Results: Our analysis reveals the impact of different mechanisms on the renewable project size in equilibrium as well as different players' preference. Assuming risk neutrality, we find that the three negotiation mechanisms lead to identical equilibrium project sizes. However, conflicts of preference for different negotiation mechanisms exist among parties. Further, buyers' perception of risks due to market uncertainty and REC market prices can harm the achievement of the sustainable goals.

3 - Building Supply Chain Resilience and Agility Using ML & AI

Vinayak Deshpande, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, Naren Agrawal, Morris Cohen

The global pandemic and other recent geopolitical events have highlighted the importance of supply chain resilience and agility. Unfortunately, many companies have failed to develop strategies that can deliver these capabilities. In particular, the most promising enablers, i.e., artificial intelligence and machine learning, cloud computing, and big data, have fallen short. In this presentation, we describe Optimal Machine Learning, a new paradigm that we have developed, that leverages the capabilities of advanced technology. We illustrate the power of this new approach for supply chain planning by reporting on two successful implementations in complex global supply chain environments. We then discuss a framework to guide efforts to design effective strategies for supply chain resilience and agility.

4 - Building Supply Chain Resilience Through Vertical Control

Ali Kaan Tuna, Tilburg University, Tilburg, Netherlands, Nitin Bakshi, Robert Swinney

We study the value of two types of vertical control—vertical integration and direct sourcing—for increasing resilience towards random raw materials shortages. We use a three-tier supply chain model in which a Tier 0 buyer sources a critical component from a Tier 1 supplier, who sources raw materials from disruption-prone Tier 2

suppliers. With vertical integration, the buyer purchases its Tier 1 supplier, taking control of its sourcing decisions. With direct sourcing, the buyer purchases raw materials from Tier 2 and sells to Tier 1. We find that either form of vertical control is most valuable when the likelihood of disruptions is moderate, with vertical integration preferred over direct sourcing for more severe disruptions. We next consider whether penalty contracts—in which the buyer charges the supplier a penalty for each unit the supplier fails to deliver—can replicate the outcome of vertical control, and find that while this is possible, the necessary non-delivery penalty may be too high for the supplier to accept, particularly when disruptions are of moderate likelihood, implying vertical control can be valuable even if penalty contracts are possible. Finally, we explore whether multi-sourcing in Tier 1 can eliminate the need for vertical control and find that while it can reduce the need for vertical control, vertical control is still optimal when disruption risk is moderate. Together, our results show that, under specific circumstances, vertical control can be a valuable addition to the portfolio of strategies firms use to mitigate disruption risk.

1 - Congestion in the Age of Uber: Medallion Management and Taxi Hailing Technology

Kaitlin Daniels, Wisconsin School of Business, University of Wisconsin, Madison, WI, United States

The introduction of Transportation Network Companies (TNCs) into ride-hailing markets poses a challenge for congestion-sensitive regulators. Many large cities have historically been served exclusively by street-hailing taxis, which, to operate, require one of a limited number of medallions issued by a regulator. TNCs differ from taxis in two important ways: (i) the regulator does not control their supply of self-scheduling drivers, and (ii) they use a more efficient hailing technology (“e-hailing”). We study how the use of two existing regulatory powers – issuing medallions and restricting taxi hailing technology – can address congestion caused by the TNC. To minimize congestion, the regulator decides how many medallions to issue and whether to improve taxi hailing by allowing taxis to e-hail. The regulator’s optimization is influenced by the equilibrium behavior of TNC drivers, who choose whether to drive, and passengers, who choose to patronize taxis or the TNC and for whom the regulator must ensure sufficiently fast pickups. In many cities, the regulator’s existing powers are sufficient to mitigate congestion caused by the TNC. This is accomplished by improving taxi hailing and reducing the number of medallions in circulation. However, our results caution that regulators should be wary of the seeming efficiency of improving taxi hailing, which may increase overall congestion. This work provides concrete recommendations to regulators, identifying when to increase or decrease the number of medallions in circulation and/or improve taxi hailing in response to the presence of a TNC.

2 - Blockchain Traceability and Customer Satisfaction: Evidence from E-Commerce

Farzad Fathi, University of Maryland, College Park, MD, United States, Jane Jiang, Jiding Zhang

Blockchain technology offers enhanced traceability and transparency, making it particularly valuable for products susceptible to counterfeiting or those for which provenance is critical. Leveraging data from an e-commerce platform that integrates blockchain-based traceability, we empirically examine the impact of this technology on customer satisfaction. To complement our empirical findings, we develop a game-theoretical model that captures the strategic role of information disclosure enabled by blockchain traceability.

3 - Order Ahead for Pickup: Promise Or Peril?

Yunan Liu, Amazon, New York, NY, United States

Mobile technologies increasingly allow customers to order ahead at quick-service restaurants, potentially reducing delay and increasing throughput. We develop a queueing-game-theoretic model to study a hybrid system where some customers order ahead and others order onsite. Surprisingly, we find that accepting all orders as they arrive and making them irrevocable can lead to lower throughput in the hybrid system than in a pure onsite system. This inefficiency persists even when queue-length information is shared with remote customers. To address this, we examine two mitigation strategies. First, allowing remote customers to cancel orders not ready upon arrival can restore the throughput advantage of ordering ahead, although it may still underperform the non-cancellation scheme. Second, implementing a rejection policy—where new remote orders are blocked once outstanding orders exceed a threshold—can improve throughput when optimally calibrated, outperforming both the pure-onsite and non-rejection hybrid schemes, though not always the cancellation scheme. We then propose an integrated mechanism that jointly optimizes both rejection and cancellation thresholds, subject to consumers’ individual rationality. This mechanism encompasses all previously considered schemes and offers the best flexibility and performance. Our findings reveal the unintended consequences of naive order-ahead implementations and provide prescriptive guidance for managing hybrid service systems to enhance throughput while maintaining service quality.

4 - Freelancers OR Employees? a Field Experiment with a Food Delivery Platform

Wee Kiat Lee, Nanyang Technological University, Singapore, Singapore, Yao Cui, Qi Li

The ongoing debate surrounding the regulation of gig platforms to classify service providers as employees rather than freelancers has generated significant industry discussions. However, the potential impact of such a transition on the operational efficiency of gig platforms is largely unknown. In this paper, we adopt an operational perspective to examine this issue. We collaborate with a food delivery platform and implement a field experiment in which orders are randomly routed to freelancers and employees. Using the experimental results, we compare the job performance between freelancers and employees, and derive insights into how a platform should adjust its operational policies when it changes the recruitment status of service providers.

5 - Implications of Worker Classification in on-Demand Economy

Zhoupeng (Jack) Zhang, University at Buffalo School of Management, The State University of New York, Buffalo, NY, United States

How should gig workers be classified, as employees or as contractors? We study this policy question by highlighting the difference between full- and part-time gig workers and focusing on the welfare of full-timers, who do gigs to earn primary incomes. We develop a multi-period game-theoretic queueing model to study market outcomes in different worker classification scenarios. We show that being classified as independent contractors is not always harmful to full-timers; they can end up with high surpluses thanks to a positive incentives de-pooling effect of part-timers’ market entry. As such, when all gig workers are reclassified as employees (as per, e.g., Assembly Bill No. 5 in California) and part-timers exit the market, full-timers can be undercut (underhired or underpaid) by their platform employer and end up with lower surpluses. When all are reclassified as “contractors+,” a UK practice that provides incomplete employee benefits but still gives workers flexibility, additional part-timers incentivized may overcrowd the platform and hinder the improvement in full-timers’ welfare. We propose two policy alternatives: (1) a Hybrid Mode that classifies full-timers as employees but part-timers as contractors, and (2) a Priority Mode that prioritizes matching full-timers with customers over part-timers. We verify that these differentiated schemes can benefit full-timers as well as other stakeholders in the market. We calibrate the parameters in our model using real-world data and illustrate our insights with simulations of Uber’s market over 137 cities in California.

1 - Survey of Data-Driven Newsvendor: Unified Analysis and Spectrum of Achievable Regrets

Zhuoxin Chen, Tsinghua University, Beijing, China, People's Republic of, Will Ma

In the Newsvendor problem, the goal is to guess the number that will be drawn from some distribution, with asymmetric consequences for guessing too high vs. too low. In the data-driven version, the distribution is unknown, and one must work with samples from the distribution. Data-driven Newsvendor has been studied under many variants: additive vs. multiplicative regret, high probability vs. expectation bounds, and different distribution classes. This paper studies all combinations of these variants, filling in many gaps in the literature and simplifying many proofs. In particular, we provide a unified analysis based on the notion of clustered distributions, which in conjunction with our new lower bounds, shows that the entire spectrum of regrets between $\frac{1}{\sqrt{n}}$ and $\frac{1}{n}$ can be possible. Simulations on commonly-used distributions demonstrate that our notion is the "correct" predictor of empirical regret across varying data sizes.

2 - Online Resource Allocation Without Re-Solving: the Effectiveness of Primal-Dual Policies

Siqi He, Duke University, Durham, NC, United States, Yehua Wei, Jiaming Xu, Sophie Yu

We study an online resource allocation problem where requests arrive sequentially over time and must be served immediately and irrevocably under resource constraints. While state-of-the-art policies, such as probabilistic re-solving (PR) and the Bayes selector, achieve constant regret, they may require re-solving large-scale linear programs (LPs) many times, making them computationally expensive. In this paper, we propose a simple primal-dual policy that requires solving the fluid linear program only once upfront and then uses dynamic dual variable updates to reflect real-time resource availability. Under a general position gap condition equivalent to existing non-degeneracy assumptions, we prove that our policy achieves constant regret independent of the time horizon - the first such guarantee for primal-dual policies in online resource allocation. Our analysis reveals that by adjusting dual variables based on actual resource consumption, the policy maintains a negative drift that pulls the dual variables back toward optimality when they deviate significantly. The policy is computationally efficient, interpretable, and well-suited for distributed implementation as resource constraints are replaced with shadow prices that guide decision-making.

3 - Throughput-Optimal Scheduling Algorithms for LLM Inference and AI Agents

Yueying Li, Cornell University, Ithaca, NY, United States, Jim Dai, Tianyi Peng

As demand for Large Language Models (LLMs) and AI agents rapidly grows, optimizing systems for efficient LLM inference becomes critical. While significant efforts have focused on system-level engineering, little is explored from a mathematical modeling and queuing perspective.

In this paper, we aim to develop the queuing fundamentals for large language model (LLM) inference, bridging the gap between the queuing theory and LLM system communities. In particular, we study the throughput aspect in LLM inference systems. We prove that a large class of 'work-conserving' scheduling algorithms can achieve maximum throughput for individual inference LLM engine, highlighting 'work-conserving' as a key design principle in practice. In a network of LLM agents, work-conserving scheduling alone is insufficient, particularly when facing specific workload structures and multi-class workflows that require more sophisticated scheduling strategies. Evaluations of real-world systems show that Orca and Sarathi-serve are throughput-optimal, reassuring practitioners, while FasterTransformer and vanilla vLLM are not maximally stable and should be used with caution. Our results highlight the substantial benefits that the queuing community can offer in improving LLM inference systems and call for more interdisciplinary development.

4 - Matching Queues, Flexibility and Incentives

Chiwei Yan, University of California Berkeley, San Francisco, CA, United States, Francisco Castro, Peter Frazier, Hongyao Ma, Hamid Nazerzadeh

Agents in online marketplaces (such as ridesharing and freelancing platforms) are often strategic, and heterogeneous in their compatibility with different types of jobs: fully flexible agents can fulfill any job, whereas specialized agents can only complete specific subsets of jobs. Convention wisdom suggests reserving agents that are more flexible whenever possible, however this may incentivize agents to pretend to be more specialized, leading to loss in matches. We focus on designing a practical matching policy that performs well in a strategic environment.

5 - Value of Sparse Structures in Dynamic Reusable Resource Allocation with Waiting

Yue Hu, Stanford University, Palo Alto, CA, United States, Jing Dong, Shixin Wang

We study the dynamic resource allocation problem in online service platforms featuring reusable resources, waiting space, and heterogeneous demands and resources. The service provider aims to balance the trade-off between maximizing revenue and minimizing waiting times across various demand types. For this problem, we propose a comprehensive framework to minimize the long-run average revenue loss and waiting cost by simultaneously designing the 1) flexibility structure, 2) admission control, and 3) scheduling policy. Our proposed flexibility structures are tailored to systems with varying levels of workload intensity, and the number of arcs in the network is linear in the number of resource and demand types. In these sparse networks, we show that simple static priority rules and threshold-based admission controls are asymptotically optimal in the many-server regimes. Furthermore, our proposed algorithm for designing system flexibility, along with the scheduling and admission control policies, is both straightforward to interpret and easy to implement. Numerical experiments demonstrate the effectiveness of our approach, particularly for smaller systems, in non-asymptotic environments.

Information and Algorithm Design in Revenue Management

Invited Session

Revenue Management

Chair: Shouqiang Wang, University of Texas Dallas, Richardson, 75080, United States

1 - Designing Pandora's Box: Product Rankings for Two-Sided Platforms

Shreyas Sekar, University of Toronto - Rotman School of Management, Toronto, ON, Canada, Yiangos Papanastasiou

With the rapid growth of e-commerce, product rankings have emerged as a primary lever used by two-sided platforms to match supply with demand. Although product rankings have been studied from a variety of perspectives, existing research typically focuses on the interaction between ranking policies and consumer search, treating the supply side of the market as exogenous. In this paper, we present a model in which both sides of the market respond strategically to the platform's ranking policy: on the supply side, sellers participate only if their earnings exceed an outside option, while on the demand side, consumers adjust their search behavior to maximize their utility. We illustrate that in such settings, intuitive policies that simply direct consumers to the sellers that best match their preferences are typically suboptimal, resulting in poor marketplace participation. Using tools from the information design literature, we propose a new framework for designing ranking policies that allow the platform to balance supply- and demand-side incentives. Building on this framework, we develop insights into the structure of optimal policies and demonstrate how these insights can be used to design policies which are easy to compute, scalable, and near-optimal in a large set of problem instances.

2 - Stationary Online Contention Resolution Schemes

Mohammad Reza Aminian, The University of Chicago, Booth School of Business, Chicago, IL, United States, Rad Niazadeh, Pranav Nuti

Online resource allocation problems are central to revenue management, where a seller with limited inventory must decide whether to fulfill stochastically arriving requests to maximize expected revenue. A prominent approach to such problems involves solving a fluid relaxation and then applying an *online contention resolution scheme* (OCRS) to implement an online policy. OCRSs not only offer strong performance guarantees but also inherently ensure fairness in allocation—an increasingly critical consideration in many applications.

Despite their appeal, OCRSs are often difficult to design and interpret. We introduce new paradigms that simplify the construction and analysis of OCRSs. First, we define **stationary OCRSs (S-OCRSs)**, which treat each incoming request as if it were the last and maintain a stationary distribution of perceived inventory over time. This framework leads to simple, interpretable allocation policies.

Second, we propose a novel surrogate model where algorithms may serve requests multiple times, which arises naturally from analyzing vanishing probability scenarios. We show how to convert such algorithms into valid OCRSs via a reduction based on *mean-preserving contractions* (MPC).

We apply these frameworks to design near-optimal, greedy-like OCRSs for various settings, including inventory of size k , achieving a selectability guarantee of $1 - 2/\sqrt{2\pi k} + O(1/k)$. Lastly, our MPC framework also provides a new proof of why a greedy algorithm based on the level of available inventory is the optimal policy, which is arguably simpler and more intuitive than the previous proofs using linear programs.

3 - The Design of Intertemporal References with Peer Effects

Lin Chen, INSEAD, Fontainebleau, France, Guillaume Roels

Goals are traditionally classified into two types: those based on task-specific or *intrapersonal* standards of competence, and those based on *interpersonal* standards of competence. The former relies on one's own past performance, while the latter is strongly shaped by the availability of information about others. Using a dynamic framework, we characterize how individual effort responds to intra- and interpersonal goals. Building on this, we demonstrate how performance transparency can serve as an intervention to promptly enhance agents' performance.

4 - Recommender Systems Under Privacy Protection

Shouqiang Wang, University of Texas Dallas, Richardson, TX, United States, Can Kucukgul, Ozalp Ozer

We study how a profit-driven online platform designs its recommender policies in response to different privacy protection regimes that grant users varying degrees of control over their personal data. We demonstrate the effective equivalence between the opt-out protection and the unprotected privacy. As a key finding, consumers' autonomy over their privacy (to the extent that they could misrepresent their personal data) may compel platforms to distort their recommender policies and lead to unintended consequences. When the recommendation plays only an informative role, such level of privacy protection deters the platform from any personalized recommendation. If the recommendation can additionally play an allocative role to control consumers' access to products, the interplay between the recommendation's informative and allocative roles may give rise to algorithmic discrimination, whereby the disadvantaged minority in the society are restricted or deprived of access to potential valuable opportunities. Ultimately, these distortions could inadvertently hurt both platforms and consumers, relative to less stringent privacy protection regimes. Counter-intuitively, enacting the recommendation's allocative role that could limit users' access to certain products in addition to its informative role can in fact benefit both the platform as well as the users, especially when users are given the autonomy over their privacy. Our findings are robust even when the products' profit margins are endogenous.

Empirical Approaches to Retail Decision-Making

Invited Session

Revenue Management

Chair: Nymisha Bandi, Stony Brook University, Stony Brook, NY, H3V1G2, United States

1 - Restaurant Density and Delivery Speed in Food Delivery Platforms

Wenchang Zhang, Indiana University Bloomington, Bloomington, IN, United States, Zhanzhi Zheng, Ruomeng Cui

With the rapid growth of food delivery platforms, understanding their operational implications for partnered restaurants is crucial. This paper compares three main externalities induced by an increase in restaurant density on a platform: customer expansion, cannibalization, and delivery pooling (i.e., drivers being in closer proximity to restaurants). Using a theoretical model, we develop testable hypotheses about the impact of these externalities on various aspects of partnered restaurants, including delivery speed (i.e., order wait time), sales, revenues, and customers' spending behaviors. Econometric analysis, based on data from a major Chinese food delivery platform, shows that as the platform's restaurant density increases, delivery speed, sales, and revenues improve for partnered restaurants. However, customers are found to opt for smaller order sizes in denser areas. The empirical evidence then indicates that delivery pooling emerges as the dominant externality compared to customer expansion and cannibalization as a platform expands regionally. We further estimate that the driver arrival speed at a restaurant and restaurant density follow an inverted-U-shaped relationship, suggesting a diminishing benefit to delivery speed from increasing restaurant density. Lastly, using instrumental variable estimation, we find that both restaurant sales and customer spending behaviors are highly sensitive to delivery speed, underscoring the dominant role of delivery pooling. Our findings highlight the importance of optimizing restaurant density for food delivery platforms undergoing expansion and recommend a focus on maintaining high restaurant density areas to maximize delivery speed. This can foster a scenario beneficial not only for platforms but also for restaurant partners and customers.

2 - Voice Chatbot Design: Leveraging the Preemptive Prediction Algorithm

Shuai Hao, Southern University of Science and Technology, Shenzhen, IL, United States, Yuqian Xu

This paper investigates the design of artificial intelligence (AI) voice chatbot systems by introducing a novel preemptive prediction feature that enhances human-AI interaction through workflow innovation. Partnering with a leading global e-commerce and logistics platform, we examine the design and performance of a novel preemptive prediction feature that proactively identifies the likely package for a customer's inbound inquiry call at the outset of the AI chatbot interaction. Interestingly, although the prediction feature does not modify the underlying technical logic used by the chatbot to resolve service inquiries, it meaningfully influences service outcomes through behavioral channels. Using detailed call-level data and a difference-in-differences estimation framework, we find that the feature improves both productivity by reducing average call duration by 5.3% and service quality by raising inquiry resolution rates by 5.0% and customer satisfaction by 4.6%. However, when predictions are incorrect, service performance deteriorates, though the losses are smaller than the gains from correct predictions. Further analysis reveals that customers with more prior

exposure to the AI chatbot benefit more from the feature, while rural users and those expressing strong initial sentiment (either positive or negative) are more adversely affected by incorrect predictions. To uncover the behavioral mechanisms underlying this effect, we show that correct predictions significantly reduce the likelihood of transfers to human agents, thereby increasing the probability that the chatbot has an opportunity to complete the service request.

3 - Bundling OR Discounting? Field Experiments for Healthy and Unhealthy Food

Nymisha Bandi, McGill University, Montreal, QC, Canada

Retailers routinely face the strategic decision of how to promote their products. Two of the most common promotion strategies are bundling and discounting. Determining which strategy is more effective, and how their effectiveness varies across product categories, is an open question in the world of retail. To address this, we conducted a multi-store field experiment with a global convenience store chain that regularly uses bundle promotions (particularly for certain unhealthy snacks). Our study focused on healthy and unhealthy food categories to understand how these promotions influence consumer behavior and financial outcomes. Specifically, we tested these strategies---discounts and bundles---applied to (i) healthy snacks, (ii) unhealthy snacks, and (iii) both categories simultaneously. For healthy snacks, we found that while discounting was more effective at boosting sales, bundling was more effective at increasing revenue and profit. Additionally, both promotion strategies for healthy snacks increased the sales of other unhealthy items, as consumers may engage in moral licensing, using their healthy purchases as justification to indulge in less healthy options. In contrast, neither promotional strategy had an effect on sales for unhealthy snacks. Based on this surprising finding, we convinced the retailer to conduct a follow-up experiment to investigate the impact of discontinuing a long-standing bundle promotion on unhealthy snacks. The results of this second experiment revealed no change in sales but an increase in revenue and profit, confirming our initial conclusion. These insights provide valuable guidance for retailers seeking to optimize promotion strategies for different product categories.

4 - Estimating Demand in the Absence of Sales and Inventory Information

Sarang Deo, Indian School of Business, Hyderabad, India, Sripad Devalkar, Aditya Jain

Unorganized retail stores in emerging economies, unlike conventional organized retail stores, are rarely equipped with point-of-sale devices. This leads to lack of data on retail sales and inventory positions that are crucial for effective upstream decisions made by the supplier. Existing studies in the area of inventory management have assumed availability of censored demand data (in the form of sales observations) and inventory data (order upto levels, inventory positions, stockout indicators, etc.). Our study, being pertinent to the context of unorganized retail, assumes the availability of only replenishment data. We begin by observing that replenishment is related to downstream sales through the retailer's inventory policy. We make structural and parametric assumptions about demand and inventory policy, and develop a methodology built on the Expectation-Maximization algorithm to jointly estimate demand and the inventory policy of the retailer.

Advances in Choice-Based Revenue Management and Assortment Optimization

Invited Session

Revenue Management

Chair: Antoine Desir, INSEAD, PARIS, France

1 - Assortment Optimization with Downward Feasibility: Efficient Heuristics Based on Independent Demands

Guillermo Gallego, Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Pin GAO, Shaoyu Wang, Gerardo Berbeglia

A core challenge in revenue management is to select a subset of products or services to offer customers to maximize a firm's expected revenue. Given the complexity of optimizing assortment decisions under intricate consumer behavior and business constraints, industry practitioners often resort to estimating product demand and optimizing decisions based on the independent demand (IDM) assumption, namely each product's demand is independent of the other offered products. To address its limitation of overlooking substitution effects, this paper proposes an IDM-based optimization variant that aligns "independent" demands with purchase probabilities for single-product offerings and uniformly modifies product revenues by a constant. For last-choice regular models that meet certain bounding conditions, our heuristic achieves the best possible performance guarantees and necessitates solving only two linear programs when the constraints are totally unimodular (TUM) and downward feasible. More generally, we propose heuristic extensions for cases where constraints are not TUM or the bounding conditions are difficult to determine. Beyond its practical simplicity, the proposed methodology also facilitates the development of efficient heuristics for several previously studied problems, either by relaxing assumptions or improving approximation ratios. Extensive computational experiments demonstrate that the proposed heuristics consistently deliver exceptional performance. Furthermore, analysis of a real-world dataset reveals that our heuristics, when derived from models with higher predictive accuracy, achieve superior optimization outcomes.

2 - Two Sides of "Hidden City Ticketing": Analysis of a Choice-Based Network Revenue Management Model

Nanxi Zhang, Ivey Business School, University of Western Ontario, London, ON, Canada, Jiacheng Guo, Bo Jiang, Zikai Xiong

"Hidden City Ticketing" (HCT) is a strategy where customers book flights with layovers at their intended destinations and skip the final leg of the journey. Empirical studies on airfare data have shown that HCT chances are very prevalent (about 15%-25%) in airline pricing. In this paper, we investigate the impact of HCT on airline revenue and discuss if the airline should eliminate all HCT chances from its price to achieve higher profit. We use a choice-based network revenue management model to characterize the airline's dynamic pricing problem. As airlines may penalize customers who purchase HCT by canceling frequent flyer miles and banning future travel with the airline, we capture customers' concerns about the risks of HCT through a choice model. Our analysis shows that adjusting prices to completely eliminate HCT chances may overly constrain the pricing strategy, and it harms the airline revenue more than customers' HCT purchase behavior. Furthermore, the impact of HCT is two-sided: While HCT can erode the airline's revenue, it can also boost revenue in some cases. In the worst case, if customers purchase HCT, the airline's revenue can be half of what it would be if customers don't purchase HCT. In the best case, the airline's revenue in the case customers purchase HCT can be twice that of the case where customers do not purchase HCT. Furthermore, the worst-case and best-case revenue bounds are both tight.

3 - Constrained Two-Sided Assortment Optimization

Ulysse Hennebelle, Cornell University, Ithaca, NY, United States, Omar El Housni, Alfredo Torrico

Two-sided matching platforms have proliferated thanks to their application in labor markets, dating, accommodation and ride-sharing. These platforms face the challenge of reducing choice congestion among popular options who receive more requests than they can handle, which leads to suboptimal market outcomes. To address this challenge we introduce a two-sided assortment optimization framework under general choice preferences and constraints over the assortments. The goal in this problem is to maximize the expected number of matches by deciding which assortments are displayed to the agents and the order in which they are shown. In this context, we identify several classes of policies that model the different levels of adaptivity that platforms can use in their design. Our goals are: (1) to measure the value that one class of policies has over another one, and (2) to solve the optimization problem itself for a given class.

For (1), we characterize the gaps between all pairs of classes, under any choice model and various types of constraints. These results showcase the benefits of each class of policies and show that a vast group of them ranges within a constant factor of the most adaptive optimal policy.

For (2), we provide algorithms that achieve constant approximation for every policy class, both in the unconstrained and constrained settings. In addition to studying various policy classes, this work is also the first to address constrained two-sided assortment optimization where the constraints apply to both sides of the market, which unveils new significant algorithmic challenges.

4 - Learning-Based Pricing Policy for Substitute Itineraries

Yue Su, Université de Lille, Inria, CRISTAL, Villeneuve-d'Ascq, France, Antoine Desir, Axel Parmentier

In airline revenue management, dynamic pricing for substitutable itineraries presents significant challenges due to the stochastic nature of customer choices. The dynamic pricing problem can be conceptualized as a Markov Decision Process with the objective of maximizing the total expected revenue over a finite selling horizon. However, the complexity of this model, characterized by its multi-dimensional state and action spaces, makes it computationally prohibitive to solve exactly, even for small-to-medium-sized instances. As a result, classic methods such as dynamic programming (DP) prove inefficient in addressing the dynamic pricing problem for larger instances.

In this work, we introduce learning-based policies tailored to the dynamic pricing problem of substitute itineraries. We proposed two different machine learning (ML) pipelines to encode pricing policy and designed tailored training processes for each of them. Compared to existing methods, our approach has two advantages: (1) benchmarking the proposed policies against the optimal pricing policy, we show that learning-based policies seem to be a good approximation for the optimal policy; (2) our learning-based policies can lead to huge speed-up in solving large-scale instances (with up to million-magnitude state space) by moving all CPU time offline.

Machine Learning and Human Incentives

Invited Session

Auctions and Market Design

Chair: Chara Podimata, MIT, Cambridge, MA, United States

Co-Chair: Ellen Vitercik, Stanford University, Stanford, CA, United States

Co-Chair: Nicolas Emmenegger

1 - Learning-Augmented Mechanism Design

Xizhi Tan, Drexel University, Philadelphia, PA, United States

In the framework of "algorithms with predictions," algorithms are augmented with a machine-learned prediction and the goal is to obtain improved guarantees when the prediction is correct (consistency) while simultaneously guaranteeing some worst-case bounds even if the prediction is arbitrarily wrong (robustness). The majority of the work on this framework has focused on online algorithms with predictions regarding future input. A subsequent line of work has focused on mechanism design, where the prediction is regarding the private information of strategic agents. In this talk, we initiate the study of online mechanism design with predictions, which combines the challenges of online algorithms with predictions and mechanism design with predictions. We consider the problem of designing a revenue-maximizing auction to sell a single item to strategic bidders who arrive and depart over time. We study the learning-augmented version of this problem, where the auction designer is given a prediction regarding the maximum value over all agents. Our main result is a strategyproof mechanism whose revenue guarantees are α -consistent with respect to the highest value and $(1-\alpha^2)/4$ -robust with respect to the second-highest value, for $\alpha \in [0,1]$. We show that this trade-off is optimal within a broad family of auctions.

2 - Gap Based Learning in Markets

Rigel Galgana, Massachusetts Institute of Technology, Cambridge, MA, United States

We consider a broad class of learning algorithms---which we dub "gap based algorithms" (GBAs)---which parameterize a learner's sensitivity and tolerance to actions' sub-optimality. At a high level, GBAs guarantee that the actions with large sub-optimality are selected with vanishing probability (pruned) while those with small sub-optimality are explored frequently. As these natural conditions are satisfied by many popular learning algorithms such as Hedge and epsilon-greedy, GBAs are ubiquitous in both theory and practice. In this paper, we analyze the game dynamics induced by GBAs in several important economic models of competition include: 1) the first price auction, 2) Bertrand pricing competition, and 3) the multi-unit uniform price auction. With some additional conditions on the GBAs' exploration and pruning rates, we show that the corresponding dynamics necessarily escape unstable equilibria. Our results have interesting implications for equilibrium selection and evolutionary stability.

3 - Learning to Price Electricity for Optimal Demand Response

Jing Shang, Stanford University, Stanford, CA, United States, Xinyang Zhou, Mohammad Mehrabi, Yue Chen, Moody Saleh, Andrey Bernstein, Stefan Wager

There is considerable interest in using time-varying electricity prices to drive consumer demand response, and better align energy demand with renewable production. However, optimal prices generally vary over time in response to complex signals such as weather forecasts, sunrise/sunset times, and day-of-week patterns; and existing methods are not able to make efficient use of such rich contextual information. Here, we propose a neural-network-based algorithm for contextual energy pricing. Our approach models the pricing problem as a Stackelberg game, and leverages a representation of its mean-field solution given in Mehrabi et al.(2024) for learning. We validate our approach by simulating the energy grid in several cities, and show that incorporating contextual information for pricing can considerably increase the value of the demand response programs.

4 - Strategy-Aware Regression Discontinuity Designs

Nicolas Emmenegger, MIT, Cambridge, MA, United States, Chara Podimata

In this work, we review regression discontinuity designs (RDDs) within a non-asymptotic minimax statistical framework using the tools of incentive-aware machine learning. We give a precise characterisation of the information complexity of estimating local treatment effects under a Lipschitz smoothness assumption. We do so under four agent behavioral models, and show that each model corresponds to the best response of a principal-agent Stackelberg game. Interestingly, we show that the minimax complexity depends on the behavioral model itself. Some models lead to the same information complexity as the non-strategic case, while some lead to irreducible bias -- and some fall in between leading to slower rates. We provide computationally tractable estimators for each setting, and demonstrate their robustness to misspecification using synthetic data. Finally, we apply our results to a popular dataset from economics, suggesting that strategic agents can skew the results of empirical studies -- and that our methods can help alleviate this.

From Digital Signals to Strategic Decisions: AI, Social Media, and the Future of Business Analytics

Invited Session

Social Media Analytics

Chair: Cuibing Wu, Framingham State University, 100 State St, Sherborn, MA, 01701, United States

Co-Chair: Esmat (Yasi) Sangari, University of San Francisco, School of Management, San Francisco, CA, United States

1 - Bridging the Gap: Advancing Diversity, Equity, and Inclusion in Corporate Innovation Through AI and Big Data Analysis

Cuibing Wu, Framingham State University, Framingham, MA, United States

This study analyzes how corporate earnings calls shape diversity, equity, and inclusion (DEI) outcomes using a dataset of over 170,000 transcripts (2013–2023) from SeekingAlpha. Leveraging large language models (LLMs) trained on DEI and innovation lexicons, we extract and assess DEI discourse through techniques such as keyword extraction, topic modeling, and sentiment analysis. We focus on four DEI dimensions: demographic representation, inclusivity initiatives, equity efforts, and future DEI outlooks. Regression models link these to innovation outcomes, revealing which communication patterns predict stronger DEI and innovation performance. The findings offer strategic insights for promoting DEI through corporate communications.

2 - Tracing Early Signals of Educational Demand Shifts in the Era of Generative AI

Ruilin Wang, UMass Lowell, Lowell, MA, United States, Ben Li

The emergence of generative artificial intelligence (AI), particularly large language models, is fundamentally altering public perceptions of the value and relevance of traditional educational pathways. As these technologies increasingly undertake complex cognitive tasks once reserved for highly educated professionals, they prompt pressing questions about which academic disciplines will remain resilient and which may face obsolescence. While prior research has largely centered on labor market disruptions or lagging institutional metrics such as enrollment trends, our study redirects attention to early-stage behavioral responses following a major AI breakthrough. By analyzing longitudinal shifts in public interest across a broad spectrum of academic programs and timeframes, we offer a novel perspective on how technological shocks shape educational demand in real time—informing institutional strategy, curriculum development, and policy adaptation.

3 - Open-Source AI Safe Engagement: An Approach to Discovering Highly Adopted and Capable Open-Source Models

Esmat Sangari, University of San Francisco, School of Management, San Francisco, CA, United States

As the number of open-source AI models on platforms like Hugging Face continues to grow, identifying which models will gain widespread adoption and ensuring they meet safety standards has become a critical challenge. In this study, we examine the dynamics of model adoption in the open-source AI ecosystem and propose a framework for predicting model popularity using a set of interpretable features. Our approach provides a scalable way to prioritize evaluation efforts and safety audits on high-impact models. The findings offer practical insights for developers, users, and platform designers aiming to promote responsible and effective participation in open-source AI communities.

4 - A Theory-Based Explainable Graph Attention Network for Detecting Misleading Forward-Looking Statements in Earnings Conference Calls

Elaheh Aghazadeh, UMass Lowell, Lowell, MA, United States

Earnings conference calls are a key venue through which corporate executives communicate forward-looking statements to investors. While these statements can offer valuable insights into a firm's future prospects, they are also prone to strategic obfuscation and linguistic manipulation that may mislead stakeholders. This study develops a theory-based, explainable Graph Attention Network (GAT) model to detect potentially misleading forward-looking statements in earnings calls and assess their relationship with subsequent financial fraud. Integrating insights from signaling theory, impression management, and deception detection, the proposed model leverages theory-informed linguistic features, such as hedging, over-positivity, and vagueness, alongside pre-trained embeddings. The dialogue structure of earnings calls is modeled as a heterogeneous graph consisting of speaker and utterance nodes, with edges encoding conversational and role-based relationships. Attention mechanisms within the GAT architecture provide interpretable insights into which linguistic cues and speaker interactions drive model predictions. Using a weak supervision strategy informed by SEC enforcement actions (AAERs), we construct a case-control dataset and evaluate the model's ability to (1) detect misleading statements and (2) predict future fraud at the firm level. The findings aim to enhance both detection accuracy and transparency, offering practical value to regulators, analysts, and investors seeking to identify early warning signs of corporate misconduct.

1 - Analytical Prediction of Optimized Processing Parameters in Metal Additive Manufacturing

Wei Huang, Georgia Institute of Technology, Atlanta, GA, United States

Metal additive manufacturing (AM) has emerged as a transformative technology for producing complex geometries with tailored mechanical properties. However, achieving optimal part quality and performance requires precise control over processing parameters such as laser power, scan speed, layer thickness, and hatch spacing. This study presents an analytical framework for predicting optimized processing parameters in metal AM, focusing on the interplay between thermal dynamics, microstructure evolution, and mechanical properties. The proposed approach integrates thermal modeling, solidification kinetics, and machine learning algorithms to identify optimized parameter sets that maximize mechanical strength. The framework is validated through experimental data from laser powder bed fusion (LPBF) of titanium alloys, demonstrating its capability to predict parameter combinations that yield superior part quality. This work provides a systematic pathway for accelerating the development of optimized metal AM processes, reducing trial-and-error experimentation, and enhancing the reliability of AM-produced components.

2 - Congestion-Focused Approach to Semiconductor Wafer Fabrication Facility Layout

Gwangjae Yu, Southern Illinois University Edwardsville, Edwardsville, IL, United States, Hyunsuk Baek, John Fowler

In a facility layout design problem for semiconductor fabrication facilities, the traditional approach has been to minimize the flow-weighted distance of material flow. Transports are conducted by an Automated Material Handling System on its internal transportation network. However, this approach often leads to significant traffic congestion, raising the question of whether minimizing flow-weighted distance is truly an effective criterion for designing facility layouts. This study proposes a novel approach to layout design for semiconductor fabrication facilities, termed "flow-balancing", to mitigate traffic congestion within the transportation system by leveraging the concept of entropy to quantify congestion in the transportation network. We present Mixed Integer Linear Programming models for designing the facility layout of semiconductor fabrication facilities under both the traditional and proposed approaches, and compare their performances using discrete event simulation. The result shows that the flow-balancing approach tends to outperform the traditional method in key performance measures of transportation system in semiconductor manufacturing facilities, with improvements of up to 11% in the total number of deliveries.

3 - A Three Dimensional Pipe Routing Problem in Semiconductor Fabrication Industry

Junghwa Lee, Korea University, Seoul, Korea, Republic of, Wonhee Cho, Hyungjoo Cha, Taesu Cheong

In this paper, we propose a three-dimensional shortest path problem involving a single origin and multiple candidate destinations for exhaust pipe routing in the semiconductor fabrication industry. While previous studies have actively addressed variations of the shortest path problem, this study focuses on extending the problem into three-dimensional space by incorporating calculations for pressure loss due to pipe length and multiple types of bend angles, obstacle avoidance, and safety standards relevant to industrial applications. To address the proposed problem, we develop a mixed-integer linear program. Noticing the problem complexity, we propose Pressure-based A* algorithm with Divide-and-Conquer strategy (PA*-DC) that utilizes 3D Pipe Routing A* (3DP-A*) algorithm iteratively. We validate the algorithms through

computational experiments using a real-world dataset provided by Samsung Electronics and compare the results with current industry de facto standards for pipe design in actual fabrication facilities.

4 - Economic Evaluation of Jit Systems

Ranli Lu, The Ohio State University, Columbus, OH, United States, Marc Posner

Just-in-Time (JIT) and Material Requirements Planning (MRP) are widely used production systems, each with specific strengths and weaknesses. While JIT favors lean practices and continuous improvement, it has difficulties when demand varies widely. In contrast, MRP is more effective when there is considerable demand variability. We explore how these two systems perform across a range of production scenarios. We derive cost formulas and analytical bounds that allow for direct comparison between the two systems. This provides practical guidance for manufacturers when deciding whether it may be economic to replace an existing JIT system with an MRP system.

1 - Optimizing Patient Logistical Decisions: Addressing the Overlooked Problem of Digital Blindness and Infrastructure Gaps in Healthcare Information Systems

Ipe Paramel, Oklahoma State University - Center for Health Systems Innovation, Tulsa, OK, United States, Marjorie Erdmann, William Paiva

Across healthcare systems, patient logistics are managed via technology platforms. In a mixed methods quality improvement (QI) study, working to reduce emergency department (ED) boarding, we identified a consistent pattern of suboptimal logistical decisions across departments, stemming not from human error, but from incomplete or poorly adapted information in electronic medical record (EMR) systems and related tools. We define this systemic issue as digital blindness (DB). By comparing delays caused by DB to other root causes, we found DB to be the leading contributor to boarding-related inefficiencies. Following targeted interventions to resolve DB, we compared pre- and post-intervention periods using logistic regression, controlling for ED volume and bed occupancy. Results showed a 13-minute per patient reduction in boarding time. Run chart analysis confirmed sustained improvements over seven consecutive months, increasing ED capacity by 689 hours over a nine-month period. This study underscores the importance of designing health information systems that align with real-time decision-making needs of frontline staff. We are now identifying DB types, mapping where and how DB erodes care delivery and hospital throughput, and testing efficient methods to resolve DB. Looking forward, we propose leveraging AI tools to monitor, detect, and preempt DB in real time, enabling proactive infrastructure improvements before patient care is compromised. This work aims to lay the foundation for intelligent, adaptive systems that optimize patient logistics across complex healthcare environments.

2 - A Data-Driven County-Level Budget Allocation Model to Manage the Opioid Crisis in West Virginia

Mahdi Saadati, Binghamton University, Binghamton, NY, United States, Ankit Bansal, Jean-Philippe Richard, Sam Workman, Gordon Smith, Henry Brownstein

West Virginia (WV) has one of the highest per-capita opioid-related mortality rates in the United States, reaching 80.9 deaths per 100,000 people in 2022. This study presents a data-driven optimization framework aimed at guiding county-level budget expenditures in WV to reduce opioid-related deaths (ORDs) and crime incidents (CIs). We begin by assembling a panel dataset covering county-level expenditures, ORDs and CIs from 2012 to 2022. To identify causal relationships between the county-level budget expenditures, ORDs, and CIs, we apply the Arellano-Bond Dynamic Panel Model. Next, we train a Tree Ensemble (TE) model to predict ORDs, and CIs based on budget expenditures and various socio-economic indicators and embed it into a Mixed Integer Linear Programming (MILP) framework, creating a robust utility maximization model to determine optimal budget expenditures. Focusing on 12 southern counties—WV's region most severely impacted by the opioid epidemic—our model suggests that different budget allocations could potentially reduce both ORDs and CIs significantly.

3 - Fedgem: a Federated Generalized Expectation-Maximization Algorithm for Mixture Models with An Unknown Number of Components

Michael Ibrahim, Georgia Institute of Technology, Atlanta, GA, United States, Nagi Gebraeel, Weijun Xie

We study the problem of federated clustering when the total number of clusters across clients is unknown, and the clients have heterogeneous but potentially overlapping cluster sets in their local data. To that end, we develop FedGEM: a federated generalized expectation-maximization algorithm for the training of mixture models with an unknown number of components. Our proposed algorithm relies on each of the clients performing EM steps locally, and constructing an uncertainty set around the maximizer associated with each local component. The central server utilizes the uncertainty sets to learn potential cluster overlaps between clients, and infer the global number of clusters via closed-form computations. We present a thorough theoretical study of our algorithm, presenting probabilistic convergence guarantees under common assumptions. Subsequently, we study the specific setting of isotropic GMMs, providing tractable, low-complexity computations to be performed by each client during each iteration of the algorithm, as well as verifying assumptions required for algorithm convergence. We perform various numerical experiments, where we empirically demonstrate that our proposed method achieves comparable performance to centralized EM, and that it outperforms various existing federated clustering methods.

4 - Optimizing Public Healthcare Investments: a Clustering-Based Approach to Reducing Waiting List TIMES in Chile

Constanza Contreras, Universidad de Chile, Santiago, Chile, Patricio Wolff, Sebastián Ríos Pérez

In Chile, the challenge of managing waiting lists in the public healthcare system has been approached through multiple strategies, including the injection of public funds to procure services from the private sector. However, the effectiveness of these interventions in reducing waiting times remains variable and often suboptimal. In this study, we present a novel optimization model designed to strategically identify clusters of patients, pathologies, and locations that yield the greatest reduction in median waiting time per unit of investment. We collected the discharges of elective surgeries in the Chilean waiting list from 2018 to 2024, which contains patient demographics, diagnosis, and intervention details, as well as the historical DRG codification. Central to our approach is the development of a cost estimation methodology that quantifies the expected expenditure associated with the resolution of each individual case on the waiting list. This enables more informed and targeted allocation of financial resources.

Our model was validated through a comparative analysis with historical budget allocation strategies. We compared the results according to expected health outcomes and maximal private sector capacity. This work contributes to the field of healthcare operations research by offering a data-driven tool for optimizing service delivery and enhancing the impact of public health investments.

5 - Nonparametric Classification on Low Dimensional Manifolds Using Overparameterized Convolutional Residual Networks

Zixuan Zhang, Georgia Tech, Atlanta, GA, United States

Convolutional residual neural networks (ConvResNets), though overparameterized, can achieve remarkable prediction performance in practice, which cannot be well explained by conventional wisdom. To bridge this gap, we study the performance of ConvResNeXts trained with weight decay, which cover ConvResNets as a special case, from the perspective of nonparametric classification. Our analysis allows for infinitely many building blocks in ConvResNeXts, and shows that weight decay implicitly enforces sparsity on these blocks. Specifically, we consider a smooth target function supported on a low-dimensional manifold, then prove that ConvResNeXts can adapt to the function smoothness and low-dimensional structures and efficiently learn the function without suffering from the curse of dimensionality. Our findings partially justify the advantage of overparameterized ConvResNeXts over conventional machine learning models.

6 - AI-Driven Dynamic Scenario Planning for Demand Forecasting

Chongwoo Park, Korea University Business School, Seoul, Korea, Republic of, Hosun Rhim

Accurate demand forecasting is critical for effective operations management, particularly in environments characterized by rapid innovation and volatile markets. Conventional forecasts extrapolate historical averages and linear trends, overlooking the nonlinear impacts of disruptive technologies, policy shifts, and evolving consumer preferences. This study proposes an AI-driven Dynamic Scenario Planning (DSP) architecture that embeds Bass Diffusion and Market Share models within the VISFER framework. The procedure proceeds through five stages: (1) influential variables—consumer taste, product attributes, cost structures, and macro indicators—are isolated through machine-learning screens; (2) system-thinking tools translate these drivers into causal networks that anchor scenario construction; (3) artificial intelligence generates diverse, data-rich narratives spanning technological, regulatory, and competitive uncertainty; (4) quantitative forecasting combines Bass diffusion, capturing innovators and imitators, with a market-share module that traces competitive redistribution during maturity; and (5) iterative evaluation updates parameters as empirical feedback accrues. Comparative experiments demonstrate that the integrated DSP approach reduces mean absolute percentage error and forecast bias relative to single-scenario baselines, while supplying granular insights into adoption pathways. Consequently, managers obtain actionable guidance for capacity sizing, resource allocation, and risk buffering under uncertainty. By enabling proactive identification of demand inflections, the architecture optimizes supply-chain operations and mitigates costs associated with over- or under-production. Beyond its practical benefit, the study contributes to operations-management scholarship by delivering a scalable, continuously learning forecasting platform calibrated for dynamic markets. Overall, the findings highlight the strategic value of fusing AI-driven analytics with scenario planning to support decisions in complex, uncertain environments across industries confronting relentless global change.

7 - On the Price of Differential Privacy for Hierarchical Clustering

Chengyuan Deng, Rutgers University, New Brunswick, NJ, United States

Hierarchical clustering is a fundamental unsupervised machine learning task of organizing data into a hierarchy of clusters. Many applications of hierarchical clustering involve sensitive user information, therefore motivating recent studies on differentially private hierarchical clustering under the rigorous framework of Dasgupta's objective. However, it has been shown that any privacy-preserving algorithm under edge-level differential privacy necessarily suffers a large error. To capture practical applications of this problem, we focus on the weight privacy model, where each edge of the input graph is at least unit weight. We present a novel algorithm in the weight privacy model that shows significantly better approximation than known impossibility results in the edge-level DP setting. In particular, our algorithm achieves $O(\log^{1.5} n / \epsilon)$ multiplicative error for ϵ -DP and runs in polynomial time, where n is the size of the input graph, and the cost is never worse than the optimal additive error in existing work. We complement our algorithm by showing if the unit-weight constraint does not apply, the lower bound for weight-level DP hierarchical clustering is essentially the same as the edge-level DP, i.e. $\Omega(n^2 / \epsilon)$ additive error. As a result, we also obtain a new lower bound of $\Omega(1 / \epsilon)$ additive error for balanced sparsest cuts in the weight-level DP model, which may be of independent interest. Finally, we evaluate our algorithm on synthetic and real-world datasets. Our experimental results show that our algorithm performs well on extra cost and has good scalability to large graphs.

Spatio-temporal Modeling and Forecasting for Energy Systems

Invited Session

Quality, Statistics and Reliability

Chair: Ahmed Aziz Ezzat, Rutgers University, Piscataway, NJ, United States

1 - Gaussian Processes (GPS) for Spatial-Temporal Power Curve Estimation

Ahmadreza Chokhachian, ISyE Georgia Tech, Atlanta, GA, United States, Roshan Joseph, Yu Ding

In this study, we address the challenge of modeling wind power curves by incorporating the effects of terrain. Unlike environmental variables such as wind speed and temperature, which vary both spatially and temporally, terrain features such as ruggedness, slope, and ridges vary between turbine locations but remain constant over time. To effectively handle these two modes of variation, we employ a Kronecker product Gaussian Process (GP) model. By jointly modeling data from multiple turbines, this approach integrates terrain information into the power curve estimation process, leading to more accurate, site-specific predictions. Moreover, it enhances the model's generalizability to turbines located in different terrains, underscoring the value of incorporating spatially-varying terrain data in wind energy forecasting.

2 - Online Changepoint Detection for Circular Data with Applications to Wind Direction

Tianyi Xu, University of Michigan, Ann Arbor, MI, United States

Online changepoint detection in circular data, such as wind direction, plays an important role in energy systems applications, including wind farm operations and wildfire risk monitoring. However, most existing online detection methods are tailored to linear data and are not directly applicable to circular domains. While a few recent studies address circular data, they often focus on detecting a single changepoint under prespecified in-control and out-of-control states. In this work, we extend an existing Bayesian online changepoint detection framework to accommodate sequential circular data. By integrating the von Mises distribution, we derive sequential updating rules and develop an approximation scheme to enable efficient online detection of multiple changepoints. Numerical experiments and a case study using wind direction data demonstrate that our method achieves low false alarm and missed detection rates while maintaining detection accuracy and responsiveness compared to existing benchmarks. This approach supports more responsive monitoring of spatio-temporal patterns in energy systems.

3 - Spatio-Temporal Forecasting for the Next-Generation of Wind Turbines: a Deep Statistical Method

Ahmed Aziz Ezzat, Rutgers University, Piscataway, NJ, United States, Feng Ye, Xinxi Zhang, Michael Stein

To unlock access to stronger winds, the offshore wind industry is advancing with significantly larger and taller wind turbines. Existing spatio-temporal forecasting methods compress the three-dimensional reality of the wind field (space $\times$ time $\times$ height) into a simpler, two-dimensional “world view” (space $\times$ time) which completely overlooks the vertical dimension of the wind field. Instead, we propose a multi-output spatio-temporal model with a multivariate, nonstationary, and state-dependent kernel that is capable of adequately modeling the complex dependencies in local wind speeds across multiple heights. Embedded within the statistical model, an advanced deep learning architecture fully exploits the wealth of exogenous information available to the forecaster (typically in the form of high-dimensional image streams) in order to learn and update the kernel parameters. Experiments using real-world data from the offshore wind energy areas in the Northeastern United States show that the wind speed and power forecasts from the proposed model are of considerably higher quality than those from prevalent time series, deep learning, and space-time methods.

4 - Enhanced Renewable Energy Forecasting Using Physics-Informed Conformal Prediction

Alireza Moradi, Georgia Tech, Atlanta, GA, United States, Mathieu Tanneau, Reza Zandeshahvar, Pascal Van Hentenryck

Accurate forecasting is critical for reliable power grid operations, particularly as the share of renewable generation—such as wind and solar—continues to grow. Given the inherent uncertainty and variability in renewable generation, probabilistic forecasts have become essential for informed operational decisions. However, such forecasts frequently suffer from calibration issues, potentially degrading decision-making performance. Building on recent advances in Conformal Predictions, this paper introduces a tailored calibration framework that constructs context-aware calibration sets using a novel weighting scheme. The proposed framework improves the quality of probabilistic forecasts at the site, regional and fleet levels, as demonstrated by numerical experiments on large-scale datasets covering several systems in the United States. The results demonstrate that the proposed approach achieves higher forecast reliability and robustness for renewable energy applications compared to existing baselines.

5 - Spatio-Temporal Statistical Analysis of Power Grid Resilience to Extreme Weather Conditions

Apoorva Narula, Georgia Institute of Technology, Atlanta, GA, United States, Feng Qiu, Yao Xie

We present a spatio-temporal statistical modeling framework to assess power grid resilience under extreme weather events, with a focus on hurricanes. Leveraging large-scale outage and meteorological data, we quantify how outage events propagate and recover across geographic regions. Our case study focuses on the Eastern and Southeastern U.S. states most affected by hurricanes between 2014 and 2022: North Carolina, South Carolina, Florida, Alabama, Mississippi, Louisiana, and Texas.

Outage events are defined as contiguous time periods with non-zero reported customer outages, delimited by zero-outage intervals. For each event, we estimate outage propagation and recovery rates at the county level, modeling them as a spatio-temporal stochastic process conditioned on weather covariates. These rates provide interpretable, region-specific resilience metrics that enable comparative analysis of system vulnerability and robustness.

To facilitate predictive capabilities, we construct a regression-based proxy for the propagation rate using meteorological variables from NOAA's High-Resolution Rapid Refresh (HRRR) dataset. This model identifies atmospheric conditions most associated with rapid outage growth, providing insights for anticipatory planning and resource allocation.

The dataset includes 20 hurricanes—ranging from Category 1 to Category 5—that primarily occurred between July and October (with Hurricane Nicole in November 2022). Since hurricanes often impact multiple states with heterogeneous effects, each state–hurricane pair is treated distinctly, resulting in 29 spatio-temporal observations. Our results support both statistical inference and engineering decision-making, offering a data-driven approach for enhancing power system resilience under escalating climate risks.

Quality, Statistics and Reliability

Chair: Elif Konyar, Georgia Institute of Technology, Atlanta, GA, 30318, United States

Co-Chair: Mohammad Bisheh, Georgia Institute of Technology, Atlanta, GA, United States

1 - Active Multi-Modal Data Fusion for Physiological Signals

Yue Zhao, Rensselaer Polytechnic Institute, Troy, NY, United States, Yinan Wang

Exploring human cognitive states through multi-modal physiological signals from multiple sources is increasingly significant in recent research. Machine learning methods often require large datasets, however, collecting such data can be costly and time-consuming. Multi-modal data fusion integrates information from diverse sources and offers a promising solution by enabling a more comprehensive understanding. However, fusing multi-modal data can usually include misleading information due to noise and data quality issues. Additionally, multi-modality datasets often contain redundant information, so it is essential to identify a subset of modalities with complementary information along with high-quality and informative data samples to improve the performance of the ML method. There are two main challenges: (1) which combination of modalities will benefit the downstream task the most, and (2) how to evaluate the informativeness and quality of data samples. We proposed a bi-level Active Multi-Modal Data Fusion framework that integrates active learning with contrastive learning to prioritize high-quality, impactful data points (lower-level optimization), while employing MaskConnect for gradient-based optimization to select the most relevant modality combinations and reduce redundancy in the dataset (upper-level optimization). Our proposed framework is validated using multi-modal physiological data collected from pilots who were tested by the simulated Instrumented Landing System (ILS), aiming to classify the level of difficulty of flight conditions. The result indicates that our framework can select the combination of modalities with complementary information and high-quality data samples to improve performance.

2 - O-Disco: Online Disentangling Signal Restoration and Corruption Identification

Deyi Kong, University of Minnesota Twin Cities, Minneapolis, MN, United States, Yifeng Wang, Shancong Mou, Jianjun Shi

The DISCO (DIsentangling Signal Restoration and Corruption Identification) method decouples the data into latent low-rank and sparse components. However, since the latent low-rank component corresponds to the nuclear norm, it requires loading the entire dataset during the optimization process. This prevents the application of DISCO to large datasets.

In this work, we introduce an Online DISCO that can process one data point or a small batch at a time, which is more efficient in terms of time and storage. We use a Frobenius norm formulation of the nuclear norm in the optimization problem, which is further solved using a block coordinate decomposition method. Simulations using the benchmark dataset BTAD verify the efficiency of O-DISCO.

3 - A Dynamic Ensemble Method for Spatio-Temporal Wind Energy Forecasting

Jiaxiang Ji, Rutgers University, Piscataway, NJ, United States, Feng Ye, Travis Miles, Ahmed Aziz Ezzat

The reliable and cost-effective operation of wind farms depends heavily on accurate wind energy forecasts across multiple look-ahead horizons, ranging from a few minutes to several days. There is an active literature on leveraging the advancements in data science to harness the multi-source information collected at, or in proximity, to the wind farms in order to make improved spatio-temporal wind energy forecasts. A central challenge in this literature is that methods optimized for short-term forecasting often perform poorly at longer horizons, and vice versa. While using separate models for different horizons is a potential solution, it can lead to discontinuities in forecasts across time and space, limiting their utility for downstream decision-making (e.g., issuing space-time scenarios with actionable uncertainty). To address this, we propose an ensemble framework that integrates two (or more) spatio-temporal models, each tailored to a specific forecast horizon. These models largely share similar structures—resulting in highly correlated outputs—but differ in their input features and parameterizations. The ensemble framework captures spatial, temporal, and cross-model correlations, and incorporates a dynamic weighting scheme that adapts to each model's changing predictive strength over time. Crucially, the method preserves probabilistic uncertainty and ensures continuous forecasts across different temporal scales. Applied to real-world wind data from the U.S. Mid-Atlantic region—an area of significant offshore wind energy potential—our approach achieves considerable improvements over standard spatio-temporal and time series forecasting methods.

4 - Improving Prediction Accuracy in Differential-Equation Based Models Using Sparse Real Observations

Soumik Sarkar, Florida State University, Tallahassee, FL, United States, Himanshu Balhara, Tapan Ganatma Nakkina, Raghav Gnanasambandam

Physics-based models, in the form of differential equations (DEs), play a vital role in modern science and engineering. These models support important decision-making, such as designing process parameters with additive manufacturing (AM), deciding policies with climate forecasting, and determining appropriate drug doses in pharmacology. However, discretization-based solvers, such as the Runge-Kutta Method, the Finite Element Method, and the Finite Volume Method, are often inaccurate in solving DE-based models. The noise in the measurement systems further contributes to the discrepancy between the solvers and real-world observations. Data assimilation techniques, such as traditional Kalman filter-based and Bayesian methods or modern neural network-based approaches, are widely prevalent to update the solution estimates of solvers with real-world observations. While the traditional methods fail to account for the inaccuracies of the solver, neural network-based approaches do not provide crucial uncertainty estimates. This work develops a novel Bayesian data assimilation method that accounts for the inaccuracies in solving the DE-based model. The case study shows accurate predictions, with uncertainty estimates, of the sparse spatio-temporal thermal data in the Directed Energy Deposition (DED) AM process by utilizing the heat transfer model. The proposed method also provides thermal gradients and cooling rates that are necessary for downstream microstructural predictions critical to quality control in metal AM.

5 - Iot Event Data Monitoring and Prediction Considering Within- and Between-Event Correlations

Zihan Yu, Tsinghua University, Beijing, China, People's Republic of, Kaibo Wang

In the era of Industry 4.0, with significant advancements in data acquisition, Internet of Things (IoT) systems are now capable of capturing a vast array of complex and diverse event data. These data often highlight sudden system anomalies that occur amidst stable signals. To address the correlations within and between events, we introduce a novel nonparametric Hawkes process model with a doubly time-dependent framework (DTNHawkes) for both baseline intensity and triggering functions,

thereby transcending the limitations inherent in traditional methodologies. Furthermore, this work develops a prediction and monitoring framework based on intensity functions estimated via a novel algorithm (DTPEM-EL), which integrates penalized expectation–maximization with the Euler–Lagrange equation. Extensive simulation experiments, conducted across a variety of scenarios, along with case studies utilizing real-world wind turbine data, have validated the efficacy of the proposed model and estimation algorithm.

6 - An Explainable AI-Driven Framework of Optimal Data Selection for Prognostics of Complex Systems

Sara Kohtz, Binghamton University, Binghamton, NY, United States, Shooq Nimri

Precise analysis and prognostics of complex systems has become an imperative research area in the field of reliability engineering. In particular, an optimal sensor network can enhance monitoring of high-risk systems across many fields. These include but are not limited to electric motors, power grids, autonomous vehicles, large-scale manufacturing, and many other concentrations. This study aims to develop a multi-fidelity modeling and data fusion framework, which can integrate data from numerous sources across different scales to achieve optimal system analysis. Within high-risk systems, there is a growing need for accurate prognostic tools that can utilize heterogeneous data from varying sources. Generalizing this framework requires techniques that optimize signals processing and sensor placement on a fundamental level. The essentials of this study lie within the scope of data selection for machine learning and data fusion models. However, the challenge of efficient data selection has yet to be formulated in the context of optimal design and sensor placement. Specifically, the proposed method can simultaneously determine the sensor network while optimizing the predictor or monitoring system. This is accomplished by using “proxy” models for data selection, and explainable AI for model transparency. The global and local explainability are provided via SHapley Additive exPlanations (SHAP) and Local Interpretable Model-agnostic Explanations (LIME) analyses, respectively. Various search algorithms are implemented to solve the generally applicable mathematical formulation, which utilizes predictor accuracy as the fitness function. Overall, this proposed method is demonstrated on fault detection of electric motors and shows potential for implementation within impactful complex systems.

Reliable Decision-Making

Contributed Session

Contributed

Chair: Yilin Wang, Simon Fraser University/Central University of Finance and Economics, Burnaby, BC, N/A, Canada

1 - Fast and Conditionally Optimal Computation of Two-Terminal Network Reliability

Jin-Zhu Yu, UT Arlington, Arlington, TX, United States

Assessing network reliability is critical for the robust design of various networked systems, but computing two-terminal (source-target) reliability is an #P-complete problem. We introduce dynamic programming (DP)-based algorithms for efficiently evaluating connectivity reliability in networks, addressing both tree-like and general topologies.

For tree-like networks, we present an asymptotically optimal DP method with linear time complexity by leveraging topological. For general networks satisfying a contraction condition ($L < 1$ where L denotes the expected reliability contribution from each node's neighbors), we develop an iterative fixed-point algorithm that guarantees convergence with bounded error, enabling polynomial-time solutions. In cases where $L \geq 1$, we develop iterative DP combined with pruning techniques to efficiently approximate reliability, particularly for large networks.

Numerical experiments on diverse networks demonstrate the effectiveness of the proposed methods, offering practical tools for scalable and robust network design.

2 - Nonparametric and Recurrent Survival Models for User Retention

Chanbeom Hur, Ulsan National Institute of Science and Technology (UNIST), Ulsan, Korea, Republic of, Sungil Kim

Measuring user retention is essential across various industries, particularly in contexts where user engagement data are available instead of explicit churn events. Rolling retention, also referred to as bounded retention, is widely adopted but exhibits significant limitations, notably its strong dependence on the observation window length and the absence of theoretical analysis. We derive the statistical properties of rolling retention, establish confidence intervals, and propose two novel retention metrics based on survival analysis. The first metric is a nonparametric estimator of the time-to-churn distribution that assumes a single churn event per user. It incorporates rolling retention as a special case and improves the accuracy of estimating the true distribution. The second metric adopts a model-based approach that accommodates recurrent churn events. This framework identifies the time-varying features that influence churn probability and quantifies the strength of these influences. In addition, it enables dynamic, user-specific retention estimates as additional data become available over time. We demonstrate the utility of the proposed metrics through simulations and real-world applications.

3 - Improving Legacy Industrial Optimization Applications with Benchmarking

Jacob Urlick, NetJets, Columbus, OH, United States, Evelyn Arrey, Ramiro Rodriguez Buno, Anil Sharma, Ted Allen

Software applications using MIP optimization to solve business problems are common in industrial settings. Despite the prevalence and importance of these systems, there is limited available research on how to improve the performance of legacy systems, as opposed to designing performant new systems. In practice, the costs and risks associated with designing new systems can outweigh the potential benefits associated with implementing a new research technique. We propose a novel framework for improving the performance of legacy MIP systems without substantially altering the model or implementing complicated custom enhancements, and we present two case studies showing how this approach may be used on both a standard academic benchmark problem set and to improve a real-world legacy optimization application regarding the scheduling of crewmembers at a fractional ownership airline.

4 - Individuals Journey Control Charting for Monitoring Entities with Reference Groups Applied to Cybersecurity&Rsquo;S Vulnerabilities

Mohammad Abdullah, The Ohio State University, Main Campus, Columbus, OH, United States, Theodore Allen

This study introduces a novel framework for individualized risk monitoring in cybersecurity using evolving probability estimates. The proposed method, called the Individuals Journey Probability (IJP) Chart, extends Statistical Process Control (SPC) to track the changing likelihood of critical events for each entity over time. To handle non-stationary environments, the approach incorporates Conditional Statistical Control, dynamically adjusting control limits based on contemporaneous reference groups. Machine learning models are employed to periodically update the estimated probabilities for each cybersecurity vulnerability. The methodology is applied to the prediction of whether specific vulnerabilities will be included in the U.S. CISA Known Exploited Vulnerabilities Catalog. The IJP Chart effectively identifies vulnerabilities with abnormal probability trajectories relative to peer groups, providing early indicators for proactive intervention. These results demonstrate the value of probabilistic control charting for real-time, entity-focused decision support in cybersecurity.

5 - Monitoring Covariance Shifts in Streaming Multichannel Profiles

Davide Forcina, University of Naples Federico II, Naples, Italy, Christian Capezza, Antonio Lepore, Biagio Palumbo

Modern industrial systems continuously produce multichannel profile data for real-time process monitoring and fault diagnosis. Although most existing techniques focus on detecting shifts in the process mean, changes in the covariance structure are equally critical, as the process behavior depends on the interactions among multiple variables.

In this work, we use functional graphical models to capture conditional dependencies in multichannel profile data, where high dimensionality and sparsity exacerbate model estimation and interpretability.

The proposed approach employs penalized likelihood ratio tests with adaptive penalty levels to detect various types of covariance changes.

Additionally, a diagnostic procedure based on change-point detection identifies which relationships have shifted. Extensive simulations and a real-world application

involving multi-channel temperature profile monitoring confirm the proposed method's effectiveness over competing methods already appearing in the literature.

6 - Towards Interpretable Maintenance Decisions: Condition Based Maintenance Optimization with Explainable Reinforcement Learning

Stephane Barde, Hanyang University ERICA, Ansan-si, Korea, Republic of

This study investigates condition-based maintenance (CBM) in systems subject to continuous-time stochastic degradation, monitored through periodic inspections using advanced sensors—such as vibration analysis, acoustic emission, oil diagnostics, and temperature measurements. Maintenance actions are determined based on real-time assessments of system health. Optimizing CBM strategies for multi-component systems presents significant challenges due to intricate economic, stochastic, and structural interdependencies among components. Focusing on k-out-of-n systems with economic dependence—a common structure in load-sharing mechanisms, wind turbines, and aircraft systems—we model the group CBM strategy as an average reward Markov Decision Process (MDP). In economically dependent systems, group replacement policies are typically more cost-effective than individual interventions. To analyze and interpret the resulting optimal CBM policy, we propose a novel approach grounded in explainable reinforcement learning (XRL), employing reward decomposition techniques. This methodology offers unique insights into the trade-offs between different reward types by decomposing the overall average reward into component-wise contributions. This enables detailed sensitivity analyses, identifying the reward components with the highest influence, and supports clearer comparisons with benchmark methods. The XRL framework enhances interpretability by revealing the rationale behind the optimal decisions relative to heuristic alternatives. Numerical experiments validate the method's ability to facilitate concise sensitivity assessments and benchmark comparisons, underscoring the practical value of the proposed approach.

7 - Congestion-Based Repair Policy for a Failure-Prone Service System with Strategic Customers

Yilin Wang, Central University of Finance and Economics, Beijing, China, People's Republic of, Jinting Wang, Lingjiao Zhang, Zhe Zhang

This study examines the decision-making interaction between a service provider adopting a congestion-based repair policy and strategic customers in a failure-prone M/M/1 queueing system. The server's lifetime is exponentially distributed, and a repair starts immediately upon server's breakdown. The repair rate is adjustable: the service provider employs a high repair rate (with a high cost) if the number of waiting customers reaches a threshold; otherwise, a low repair rate (with a low cost) is adopted. We aim to find the optimal congestion-based repair policy by taking customers behavior into account under two different information scenarios. To begin with, the Nash equilibrium strategies and socially-optimal strategies in the unobservable case are derived. Both follow-the-crowd and avoid-the-crowd behaviors are found coexisted in the customer's equilibrium joining strategy. Two special models, classic repair model (when the threshold approaches 0) and delayed repair model (when the low repair rate approaches 0), are discussed extensively. The classic repair policy maximizes throughput but incurs the highest costs, while delayed repair minimizes costs at the expense of throughput. The proposed congestion-based repair strategy balances these trade-offs, achieving intermediate throughput and cost levels. Notably, it can increase profits by up to 34.4% compared to classic repair, with its effectiveness amplified under high-cost scenarios. By comparing the unobservable case with the almost unobservable counterpart, we demonstrate that hiding server state information when prices are low and disclosing server information when prices are high can increase profit for service provider, but at the expense of reducing social welfare.

1 - Designing Effective Fundraising Campaigns: Behavioral Insights

Pramit Ghosh, The University of Texas at Dallas, Dallas, TX, United States, Ignacio Rios, Anyan Qi

This study examines how fundraisers maximize donations under budget constraints, focusing on financial incentives (matching or gift unlock) and solicitation methods (simultaneous or sequential). Using a game-theoretic model and laboratory experiments, we provide insights into effective fundraising strategies and behavioral deviations in donor responses.

2 - AI-Powered Philanthropy: Effects on Volunteer Productivity

Vinit Tipnis, Carlson School of Management, University of Minnesota, Minneapolis, MN, United States, Eunae Yoo, Gloria Urrea, Fei Gao

Nonprofit organizations are incorporating AI to enhance volunteer performance. Given that volunteers are motivated by generating impact and altruism, the effect of AI in the volunteering context is an open question. We answer this using data from an online volunteering platform that implemented an AI tool that complements volunteers' work.

3 - Improving Food Security with Scheduled Neighborhood Grocery Delivery

Yeonjoo Lee, University of Minnesota, MINNEAPOLIS, MN, United States, Karen Donohue

Food security is a pressing concern in the US, with 13.5% of its population identified as food insecure. While online grocery delivery has recently surfaced as a potential solution, the high delivery fees and markup pricing typical of most on-demand delivery models (e.g., Instacart) pose critical cost barriers for low-income populations. This study examines how a novel grocery delivery model, called "scheduled neighborhood delivery," which consolidates nearby grocery orders and delivers on a weekly schedule, can be a better alternative for the food security problem. In collaboration with a startup grocery delivery platform utilizing this service, we investigate the potential operational and customer well-being benefits of this new delivery service. First, using work measurement data, we estimate the magnitude of operational efficiency increase allows scheduled neighborhood delivery to charge lower the shipping fees. Next, we conduct controlled experiments explore the impact of alternative online grocery delivery designs on consumer purchase behavior, with a focus on healthy food selection. Results show the potential for increased healthy food choices under the scheduled neighborhood delivery model compared to the on-demand delivery model, especially for planned grocery purchases.

4 - Reference-Dependent Effects in Volunteering: Expected vs. Experienced Effort

Gabriel Pensamiento, University of Pittsburgh Katz Graduate School of Business, Pittsburgh, PA, United States, Mahyar Eftekhari, Leon Valdes

Humanitarian and nonprofit organizations often rely on volunteer labor to accomplish different tasks. We design an incentivized laboratory experiment to study how someone's volunteering experience being above or below effort expectations affects their decision to volunteer again. In doing so, we study the role of reference-dependent preferences in a not-for-profit setting, which is not well understood in the literature. We also aim to shed light on which responses may be unique to (or more pronounced in) a volunteering setting by comparing our results against a similar task in a for-profit context.

1 - The Impact of Loyalty Program on Gig Workers: Evidence from a Natural Experiment**Jiaxin Lei, Hong Kong University of Science and Technology, Hong Kong, Hong Kong, Gen Li, Jing Wang, Yao Zhao**

The rapid growth of on-demand delivery platforms has transformed labor dynamics within the gig economy, introducing new challenges in motivating a flexible, independent workforce. While prior literature has focused on incentive schemes such as surge pricing, penalties, and rating systems, we investigate the causal effect of a loyalty program that enables gig workers to earn virtual points by completing orders and redeem them for rewards. Leveraging a unique dataset from a major Asian online delivery platform, we assess how the program influences riders. We exploit the staggered rollout of the loyalty program across riders by comparing behavioral changes between riders who receive loyalty points and those who do not. The findings suggest the loyalty program leads to longer work durations and more delivery order volume. Further analysis reveals simply allocating virtual points does not produce a significant effect on riders. Instead, the positive overall impact is primarily driven by the redemption process. More interestingly, riders shift their behavior by delivering more small, lightweight, and short-distance orders. The pursuit of greater order quantity has led riders to accept more small orders, thereby decreasing their earnings per unit of time. While riders are working for longer durations, their tendency to take on smaller orders has not yielded higher total earnings. Compared to full-time and experienced riders, the program has a greater impact on elite freelance and inexperienced riders. These findings deepen our understanding of loyalty programs' effects on gig workers and offer insights for platforms aiming to boost productivity through flexible incentives.

2 - Reimagining Digital Markets: Platform Dominance vs. Open-Network Models**Shailender Joseph, University of Texas at Dallas, Richardson, TX, United States, Kai Sun, GANESH JANAKIRAMAN, Vijay Mookerjee**

In this work, we contrast the traditional “walled-garden” architecture epitomized by Amazon – where one firm owns the marketplace, controls the buyer interface, and levies non-negotiable commissions – with the Open Network for Digital Commerce (ONDC), an open protocol that functions like a shared system of digital railroads. Networks like ONDC decouple the buyer-side interactions and seller-side functions, making every seller discoverable to every buyer and preventing any single intermediary from sitting at the center of each transaction. Because this network-based paradigm is still in its infancy, its economic impact remains largely uncharted. Our work constructs a game-theoretic framework to quantify how migrating from a closed platform to an open network reshapes seller surplus, buyer welfare, and intermediary revenues and pinpoints the conditions under which each market design yields superior efficiency for e-commerce participants.

3 - Genai in Creative Production: Does It Narrow the Gap Between High- and Low-Skill Creators?**Zhen Yan, University of Texas at Dallas, Richardson, TX, United States, Jianqing Chen, Srinivasan Raghunathan**

The rapid development and widespread adoption of AI are transforming many industries, including creative arts and software—fields traditionally regarded as strongholds of human

creativity. A central question that remains debated is whether AI will democratize creative production by narrowing the output gap between high-skilled and low-skilled creators. This study investigates how AI adds value to the creative process and how it influences the product-value gap across skill levels. We model creative products as having two key attributes: ideation and execution. AI affects both through two distinct mechanisms: automation, which substitutes for certain execution tasks, and augmentation, which enhances creators' ideation capabilities. We find that AI consistently improves product value for creators at all skill levels. However, the magnitude of this improvement varies across creators: AI tends to widen the product-value gap when the high-skilled creator is ideation savvy (i.e., holds a greater advantage in ideation than execution) or when the high-skilled creator is execution savvy, but the automation is relatively weak. In other scenarios, AI may instead narrow the gap. These outcomes are driven by shifts in effort allocation, as AI both reduces the need for human effort in execution and increases the effectiveness of ideation. As a result, creators reallocate effort from execution to ideation. The widening of the gap may result from growing disparities in both attributes—or from ideation alone—or from increased complementarity between ideation and execution.

4 - Beyond Taste: Leveraging LLMs to Mitigate Bias in Online Reviews**Di Yuan, University of Illinois Urbana-Champaign, Urbana, IL, United States**

Online reviews heavily influence what we buy, especially for experience goods. But these reviews often contain hidden biases that can unfairly skew our perception of a product. Our study zeroes in on taste-based bias, where a reviewer's personal preferences—rather than objective quality—cloud their judgment. We're using movie reviews to explore how individual tastes can overshadow objective assessments of cinematic quality.

We've developed a new approach that uses **large language models (LLMs)** to pinpoint and rectify this taste-based bias. Our method involves fine-tuned transformer models that learn to differentiate between genuine critiques of quality and evaluations driven purely by personal preference. This is achieved by analyzing linguistic patterns, the attribution of sentiment, and the specific focus of the content. We design this method to pinpoint reviews where personal taste disproportionately impacts ratings and subsequently generate bias-corrected versions that emphasize objective product attributes.

Preliminary results indicate a significant enhancement in review quality metrics and a reduced variance in product ratings following bias correction. This study contributes to the burgeoning field of automatic content moderation and offers practical tools for platforms seeking to improve the reliability of their review systems. Furthermore, our findings have important implications for the design of recommendation systems, market research, and the analysis of consumer behavior in digital marketplaces.

Generative Models for Statistics and OR

Invited Session

Data Mining

Chair: Yao Xie, Georgia Institute of Technology, Atlanta, GA, United States

1 - Guided Diffusion for Statistical Inference**Yuchen Wu, University of Pennsylvania, Philadelphia, PA, United States**

Diffusion models benefit from instillation of task-specific information into the score function to steer the sample generation towards desired properties. Such information is coined as guidance. For example, in text-to-image synthesis, text input is encoded as guidance to generate semantically aligned images. Proper guidance inputs are closely tied with the performance of diffusion models. A common observation is that strong guidance promotes a tight alignment to the task-specific information, while reduces the diversity of the generated samples. In this paper, we provide the first theoretical study towards the influence of guidance on diffusion models in the context of Gaussian mixture models. Under mild conditions, we prove that incorporating diffusion guidance not only boosts prediction confidence but also diminishes distribution diversity, leading to a reduction in the differential entropy of the output distribution. Our analysis covers the widely used DDPM and DDIM sampling schemes, and leverages comparison inequalities in differential equations as well as the Fokker-Planck equation that characterizes the evolution of probability density function, which may be of independent theoretical interest.

2 - Diffusion Transformers for Imputation: Statistical Efficiency and Uncertainty Quantification**Zeqi Ye, Northwestern University, Evanston, IL, United States, Minshuo Chen**

Imputation methods play a critical role in enhancing the quality of practical time-series data, which often suffer from pervasive missing values. Recently, diffusion-based generative imputation methods have demonstrated remarkable success compared to autoregressive and conventional statistical approaches. Despite their empirical success, the theoretical understanding of how well diffusion-based models capture complex spatial and temporal dependencies between the missing values and observed ones remains limited. Our work addresses this gap by investigating the statistical efficiency of conditional diffusion transformers for imputation and quantifying the uncertainty in missing values. Specifically, we derive statistical sample complexity bounds based on a novel approximation theory for conditional score functions using transformers, and, through this, construct tight confidence regions for missing values. Our findings also reveal that the efficiency and accuracy of imputation are significantly influenced by the missing patterns. Furthermore, we validate these theoretical insights through simulation and propose a mixed-masking training strategy to enhance the imputation performance.

3 - Flow Generative Models for High-Dimensional and Multi-Modal Statistical Sampling**Dongze Wu, Georgia Institute of Technology, Atlanta, GA, United States**

Sampling from high-dimensional, multi-modal statistical distributions remains a fundamental challenge across domains such as statistical Bayesian inference and physics-based machine learning. In this talk, we present Annealing Flow (AF), a method built on Continuous Normalizing Flow (CNF) for sampling from high-dimensional and multi-modal distributions. AF is trained with a dynamic Optimal Transport (OT) objective incorporating Wasserstein regularization, and guided by annealing procedures, facilitating effective exploration of modes in high-dimensional spaces. Compared to recent NF methods, AF greatly improves training efficiency and stability, with minimal reliance on MC assistance. We demonstrate the superior performance of AF compared to state-of-the-art methods through experiments on various challenging distributions and real-world datasets, particularly in high-dimensional and multi-modal settings. We also highlight AF potential for sampling the least favorable distributions.

4 - Interactive Decision-Making Using Autoregressive Generation**Hongseok Namkoong, Columbia University, New York, NY, United States**

AI agents interacting with the real-world have to grapple with a perpetual lack of data in ever-changing environments. Interactive decision-making requires going beyond knowledge distillation: an intelligent agent must comprehend its own uncertainty and actively gather information to resolve it. Despite exhibiting impressive capabilities in basic knowledge work, state-of-the-art AI systems struggle to articulate their own uncertainty, e.g., OpenAI recently noted its latest agentic system “DeepResearch often fails to convey uncertainty accurately”.

This talk covers a series of recent works that tackle the central challenge of uncertainty quantification in natural language-based interactive decision-making problems. Instead of modeling latent environment parameters, we view uncertainty as arising out of missing future outcomes and quantify it through autoregressive sequence generation—iteratively predicting the next outcome given the past. By adapting to new information through in-context learning rather than cumbersome posterior inference, our approach seamlessly scales to problems involving unstructured data, e.g., adaptive student assessment involving text and images. Formally, we establish a reduction from online decision-making to offline next-outcome prediction, enabling us to leverage the enormous datasets and computational resources dedicated to improving sequence prediction for interactive decision-making tasks.

5 - Finite-Time Convergence Guarantees for Masked Diffusion Models**Yingbin Liang, The Ohio State University, Columbus, OH, United States, Yuchen Liang, Renxiang Huang, Lifeng Lai, Ness Shroff**

Masked diffusion models (MDMs) have recently emerged as a powerful class of generative models for discrete tasks such as language generation, code synthesis, and molecular design, by iteratively denoising masked tokens. Despite their impressive empirical performance, a rigorous theoretical understanding of their convergence behavior and error dynamics remains largely unexplored. In this work, we provide the first finite-time error bounds and convergence guarantees for MDMs. We first analyze the convergence of the forward process, where we address a key challenge posed by the degeneracy of the masking stationary distribution in the KL divergence by introducing a novel surrogate initialization distribution. We then establish the first convergence guarantees for both the ϵ -leaping and uniformization samplers for MDMs, showing improved rates compared to those using uniform rate matrices. Furthermore, under mild assumptions, we establish convergence without the need for early stopping. Our analysis introduces several new technical tools to address challenges unique to MDMs, including a Jensen-type argument for bounding forward process convergence, novel techniques for bounding masking score functions, and a non-divergent upper bound on the score near initialization that removes the need of early-stopping.

Evaluation and Scalability of LLM Prompting

Invited Session

Data Mining

Chair: Hongyang Zhang, Northeastern University, Boston, MA, United States

Co-Chair: Hongseok Namkoong, Columbia University, New York, NY, United States

1 - Past Experience Accelerates LLM Reasoning**Bo Pan, Emory University, Atlanta, GA, United States, Liang Zhao**

Allocating more compute to large language models (LLMs) reasoning has generally been demonstrated to improve their effectiveness, but also results in increased inference time. In contrast, humans can perform tasks faster and better with increased experience and practice. Hence, we aim to investigate the question: Can LLMs also become faster at reasoning through recurrent practice on relevant tasks, and if so, how?

We first formalize the problem setting of LLM reasoning speedup systematically in the dimensions of task relevancy and compute budget calculation. We then propose framework to implement and benchmark such reasoning speedup behaviour based on adaptive compute allocation and memory mechanisms. We further conduct comprehensive experiments to benchmark such behaviour across different question similarity levels, memory methods, and reasoning methods. Results show that LLMs can generally reason faster with practice, achieving up to a 56% reduction in compute cost when equipped with appropriate memory and reasoning methods.

2 - Label-Invariant Sharpness Regularization to Mitigate Grokking in Mathematical Reasoning

Zhenshuo Zhang, Northeastern University, Boston, MA, United States

Mathematical reasoning is a central aspect in the evaluation of large language models. A phenomenon observed in modular arithmetic tasks, a basic math problem, is grokking, where training performance converges to perfect accuracy but test performance does not, until after an extended period. Understanding grokking and, more generally, the generalization of LLMs for math reasoning remains a mystery. This paper examines the presence of invariant structures in math reasoning, including arithmetic and graph-algorithmic tasks. We find that the sharpness of the loss surface, as defined by its Hessian trace, is much lower along label-invariant input directions than a random input direction. Let g denote a label-invariant transformation and x denote an input. A label-invariant direction refers to a direction that moves along the augmentation of x via g , minus x . Thus, the "label-invariant Hessian trace" provides a more precise sharpness measure for the loss landscape of math reasoning tasks. Motivated by this finding, we design a new regularization method to penalize the Hessian trace of the loss surface along label-invariant input directions. First, we interpolate between x and an augmented version of x using g . Second, we compute the gradient at the interpolating point while adding noise to the model weights. We also provide a generalization bound that depends on a Hessian distance measure for learning invariant function classes to tie this together. For six text-based arithmetic and graph-algorithmic tasks, our approach improves the test accuracy of LLMs by 16.5% and by 69% on out-of-domain samples.

3 - AI-Powered Recruitment Evaluation: from Intuition-Based to Data-Driven Hiring Decisions with A Generative Agent

Jaeyeon Yoon, Yonsei, Seoul, Korea, Republic of, Young Il Oh, Hyunsoo Yoon

Traditional hiring relied heavily on human intuition, resulting in manual and subjective decisions with limited explainability. We developed a generative AI assistant that analyzes resumes, summarizes competencies, verifies facts, assesses job and culture fit, recommends roles, and generates tailored interview questions. Comparing recruiter choices before and after AI use highlights the need for structured, explainable support in hiring.

4 - Scaling up Inference via Gradient Estimation

Hongyang Zhang, Northeastern University, Boston, MA, United States

This paper introduces an algorithm to select demonstration examples for in-context learning of a query set. Given a set of n examples, how can we quickly select k out of n to best serve as the conditioning for a downstream task? This problem has broad applications in prompt tuning and chain-of-thought reasoning, to name a few. Since model weights remain fixed during in-context learning, previous work has sought to design methods based on similarity scores measured in the input embeddings. This work proposes a new approach based on gradients of the model output taken in the input embedding space. Our approach estimates model outputs through a first-order approximation using the gradients. Then, we apply this estimation to multiple randomly sampled subsets. Finally, we aggregate the sampled subset outcomes to form an influence score for each demonstration, and select k most relevant examples. This procedure only requires pre-computing model outputs and gradients once, leading to a linear-time algorithm relative to model and training set sizes. Extensive experiments across various LLMs and datasets validate the efficiency of our approach. We show that the gradient estimation procedure yields approximations of full inference with less than 1% error across six datasets. This allows us to scale up subset selection methods that would otherwise run full inference by up to 37.7 times on LLMs with up to 34 billion parameters, and outperform existing selection methods based on input embeddings by 11% on average.

Design, Behavior, and Performance Topics in the Knowledge Economy

Invited Session

Technology, Innovation Management and Entrepreneurship

Chair: Sina Khorasani, Vanderbilt University, Nashville, TN, United States

Co-Chair: Konstantinos Stouras, UCD Michael Smurfit GSB, Dublin, Ireland

1 - A Machine Learning Framework for Project Performance Prediction, Interpretation, and Inference

Xiaochen Kev Gao, University of California, San Diego, La Jolla, CA, United States, Sina Khorasani, Vish Krishnan, Lakshminarayana Nittala, Siqi Wang

In this paper, we offer a data-driven AI-based analytic pipeline to predict, interpret, and infer the nature and severity of cost or schedule overrun a project will experience. We integrate large language models (LLMs) in the pipeline for data augmentation and prediction, and operate on unstructured data in addition to tabular data. Our analysis and results underscore the need for the government and other enterprises to collect and utilize the data for predictive and causal analysis and to develop more nuanced approaches and incentives to tackle cost and schedule overruns in real-world project settings.

2 - Enhancing the Entrepreneurial Process with Large Language Models

Karthik Ramachandran, Georgia Institute of Technology, Atlanta, GA, United States, Nitin Joglekar

We examine how Large Language Models (LLMs) support the entrepreneurial process by facilitating the creation and exploration of opportunities. An experimental study reveals both their potential and challenges, and shows how different training approaches influence the effective use of LLMs in entrepreneurial contexts.

3 - How Do Loyalty Programs Affect Multichannel Bookings? An Empirical Investigation

Shuaishuai Yang, UCL School of Management, London, United Kingdom, Antoine Feylessoufi, Ersin Korpoglu

With the increased market power of online travel agencies (OTA), the hotel industry faces a new and important trade-off when working with OTAs: Potentially increasing sales at the expense of sizeable commission fees. In response, major hotel groups turn to loyalty programs, giving discounts to loyalty members for booking through their direct channels. In this paper, we investigate how successful loyalty discounts are in their goal to sway customers from OTAs to direct channels. Using a unique dataset obtained from a major hotel group, we empirically investigate how loyalty discounts affect customers' booking channel choices. We utilize a quasi-natural experiment based on an exogenous change of the loyalty discount in a subset of hotels in our dataset to construct a difference-in-difference model. We find that a larger loyalty discount raises bookings from the direct channel with loyalty membership, lowers bookings from the direct channel without loyalty membership, and has no significant effect on OTA bookings. This suggests that a substitution effect only occurs within the direct channel and, surprisingly, not cross-channels. Our results indicate that discount-based loyalty memberships do not have the intended effect of swaying customers from OTAs toward direct channels. Instead, directchannel customers utilize the loyalty program more, which may end up lowering hotel revenues. Therefore, our study suggests that the hotel industry should carefully assess the effectiveness and the design of their loyalty programs by factoring in their multichannel setting.

4 - On Repeat: Iteration as a Key to Innovative Performance?

Christian Jost, University of Augsburg, Augsburg, Germany, Evgeny Kagan, Sebastian Schiffels, Tobias Lieberum

Motivated by the rise of iterative project management, we examine how workflow -- iterative or sequential -- affects innovative behavior and performance through a series of laboratory experiments. Our first experiment shows that, in an open-ended creative challenge, iterative task completion outperforms sequential task completion. In the second experiment, we show that the advantage of the iterative workflow extends to innovation settings that do not involve idea generation. A key driver of this result is that iterative work results in frequent task switching, encouraging a broader search for the best solution. Our third experiment dives deeper into the search process and shows that sequential work indeed leads to more myopic idea refinement behaviors, often resulting in suboptimal outcomes. Overall, our results suggest that the iterative workflow enhances performance across diverse innovation settings, though there are some key limitations: (1) the iterative workflow helps to achieve quick gains, but its performance advantage narrows over time. Consequently, workflow effects are stronger when balanced performance across project components is required, but weaker

when excellence in one component can offset poor performance in others. (2) The iterative workflow offers little benefit in tasks that do not require the broad exploration of solutions. (3) The iterative workflow can be harmful in settings with strong technological path dependencies.

5 - Influence Structures and Collective Action In Online Communities: Evidence from Reddit's R/place

Tian Chan, Emory University, Atlanta, GA, United States, Shizhen Chen, Anandhi Bharadwaj

Online communities frequently grapple with two fundamental challenges in collective action projects: coordinating strategy and mobilizing broad-based participation. This study posits that the structure of influence within an online community significantly impacts its efficacy in addressing these challenges. Specifically, we argue that communities with more hierarchical influence structures—where a concentrated few significantly shape others' behavior—excel at coordinating strategy but struggle with mobilizing participation. Conversely, flatter structures may face initial coordination hurdles but foster greater participation. We test these hypotheses using empirical data from Reddit's 2022 r/place event, where communities mobilize their members to construct artwork pixel-by-pixel on a shared digital canvas. Our findings reveal several key insights: Communities with more hierarchical influence structures demonstrate faster strategic decision-making, evidenced by earlier project initiation and more rapid initial progress toward their objectives. However, this early advantage shrinks as inter-community competition intensifies, increasing the imperative to mobilize marginal members. In these more demanding phases, flatter influence structures surpass their hierarchical counterparts in project progression rates. The performance improvement of flat communities is particularly pronounced when they possess a large contingent of marginal members who subscribe to community updates but do not actively participate in discussions. These findings advance our understanding of online community dynamics and offer crucial implications for the design and management of various online collective action projects, such as crowdfunding campaigns, online petitions, digital protests, and coordinated stock trades.

FICO/Gurobi Optimization

Invited Session

Technology Showcase

Chair: Loraine Coleman, INFORMS, 5521 Research Park Drive, Catonsville, MD, 21228, United States

1 - Reducing Time-to-Value with Fico Xpress Optimization Suite and Gen AI

Carlos Zetina, FICO Xpress Optimization, Québec, QC, Canada

Time to Value measures how long it takes for technology projects to begin providing business value. Three critical milestones to achieve this are model creation, validation, and deployment. In this showcase, we'll show how FICO Xpress Optimization Suite shortens Time to Value and supercharges Return on Investment (ROI) by providing a unified platform for development, validation, and deployment. We'll show how FICO's suite of products and Gen AI come together to turbocharge building and adoption of enterprise optimization applications deployable on any tech stack, be it server-less or via virtual machines, hosted on any cloud provider or on-premises infrastructure.

Hear from Rusty Burlingame from Southwest Airlines, on how Southwest is using Xpress to improve customer experience, enhance employee engagement, and streamline operations to maximize revenue and support growth.

2 - Cracking the Vault with Gurobot: Generative AI and the Future of Mathematical Modeling

Cara Touretzky, Gurobi Optimization, Santa Fe, NM, United States

Discover how Gurobi is exploring the use of generative AI to support and streamline the modeling of mathematical optimization problems. Through the lens of a hands-on museum heist challenge, we'll walk through examples of AI-assisted modeling across varying levels of complexity. We'll highlight current capabilities, acknowledge present limitations, and offer a glimpse into where we're headed next as we expand the role of AI in the modeling workflow.

Advances in Quantum Computing Optimization

Invited Session

Committee's Choice

Chair: Tamás Terlaky, Lehigh University, 200 W. Packer Avenue, Bethlehem, PA, PA, 18015, United States

1 - A Quantum Central Path Method for Linear Optimization

Giacomo Nannicini, University of Southern California, Los Angeles, CA, United States

We propose a novel quantum algorithm for solving linear optimization problems by quantum-mechanical simulation of the central path. While interior point methods follow the central path with an iterative algorithm that works with successive linearizations of the perturbed KKT conditions, we perform a single simulation working directly with the nonlinear complementarity equations. This approach yields an algorithm for solving linear optimization problems involving m constraints and n variables to ϵ -optimality using, approximately, $O(\sqrt{m+n} \|R_1\|/\epsilon \text{nnz}(A))$ elementary gates, where $\text{nnz}(A)$ is the number of nonzero elements of the constraint matrix, R_1 is the norm of the optimal solution. Our scheme does not require QRAM.

2 - On Accelerating Optimization Methods by Quantum Linear Algebra

Mohammadhossein Mohammadisiahroudi, Lehigh University, Hatfield, PA, United States, Tamás Terlaky, Zeguan Wu, Pouya Sampourmahani

Solving systems of linear equations is a core component of many optimization algorithms. Quantum linear algebra techniques, especially quantum linear system algorithms (QLSAs), offer the potential to significantly accelerate these computations. One area where this promise is particularly compelling is in Quantum Interior Point Methods (QIPMs), which aim to solve large-scale conic optimization problems more efficiently by leveraging QLSAs. While QIPMs offer favorable scaling with respect to dimension, they face several challenges. These include sensitivity to problem conditioning, errors introduced by quantum tomography, and the limitations of current quantum hardware. Recent research has addressed some of these issues through various strategies: iterative refinement improves accuracy of solution, preconditioning enhances the conditioning of systems, and linear system reformulations maintains feasibility even with error at each iteration. A particularly promising development is the almost-exact QIPM framework, which is more quantum-enhanced as classical matrix-vector (mat-vec) operations are replaced with quantum mat-vec operations. This approach not only reduces noise sensitivity but also achieves *optimal dimension scaling*, leading to a clear quantum advantage for linear optimization. Additionally, in the domain of PDE-constrained optimization, which is crucial in engineering and scientific computing, QLSAs can solve the adjoint and forward equations efficiently without requiring tomography. This results in an exponential quantum speed-ups with respect to number of state variables. In this talk, I will provide an overview of these developments, discuss their implications, and outline open questions and future directions in applying quantum linear algebra to accelerate optimization.

3 - Exponential Quantum Speedup in Optimization: Theory and Practice

Xiaodi Wu, University of Maryland, College Park, College Park, MD, United States, Jiaqi Leng, Yufan Zheng

Harnessing the power of quantum algorithms to tackle optimization problems is a critical frontier with transformative potential for both theory and real-world applications. Traditional approaches to quantum speedups in optimization typically focus on accelerating specific subroutines within classical algorithms, while preserving the overall algorithmic structure and solution quality. In contrast, we introduce Quantum Hamiltonian Descent (QHD)—a fundamentally quantum optimization framework derived from the path integral of dynamical systems associated with classical optimization methods.

We establish both strong theoretical foundations and empirical evidence for the effectiveness of QHD, based on current analytical tools and available quantum hardware. Specifically, we prove that QHD achieves an exponential quantum-classical separation for a class of oracular continuous optimization problems. Beyond the oracular setting, we demonstrate that QHD can efficiently solve a family of nonconvex degree-4 polynomial optimization problems with exponentially many local minima—instances for which state-of-the-art classical solvers, including Gurobi, appear to require super-polynomial time.

To enable practical implementation, we propose a novel Hamiltonian embedding technique, and experimentally realize QHD on an analog quantum Ising simulator with over 5000 spins, solving nonconvex quadratic programming (QP) problems of up to 75 dimensions. To support broader adoption, we also release QHDOPT, a user-friendly software package built on the QHD framework, designed to empower domain experts in leveraging quantum optimization.

4 - Operator-Level Quantum Acceleration of Non-Logconcave Sampling

Lin Lin, UC Berkeley, Berkeley, CA, United States

Sampling from probability distributions with a continuous potential, is a fundamental task across physics, chemistry, biology, computer science, and statistics. However, when the potential is non-convex, the resulting distribution becomes non-logconcave, and classical methods such as Langevin dynamics often exhibit poor performance. We introduce the first quantum algorithm that provably accelerates a broad class of continuous-time sampling dynamics. For Langevin dynamics, our method encodes the target Gibbs measure into the amplitudes of a quantum state, identified as the kernel of a block matrix derived from a factorization of the Witten Laplacian operator. This connection enables Gibbs sampling via singular value thresholding and yields the first provable quantum advantage with respect to the Poincaré constant in the non-logconcave setting. Building on this framework, we further develop the first quantum algorithm that accelerates replica exchange Langevin diffusion, a widely used method for sampling from complex, rugged energy landscapes.

5 - Recent Progress in Quantum Approximate Optimization

Ruslan Shaydulin, JPMorgan Chase, New York, NY, United States

I will present recent research progress in quantum approximate optimization at the Global Technology Applied Research center of JPMorganChase

Group Decision and Negotiation

Chair: Eduarda Frej, Universidade Federal de Pernambuco, Recife, Brazil

Co-Chair: Danielle Costa Morais, Universidade Federal de Pernambuco, Recife, N/A, Brazil

1 - Multicriteria Group Decision-Making Using Flexible and Interactive Tradeoff with Partial Preference Information

Adiel De Almeida, Universidade Federal de Pernambuco, Recife, Brazil, Eduarda Frej, Jonatas Almeida, Ana Paula Cabral Seixas CostaCosta

The presentation shows a new Multicriteria Group Decision-Making (MCGDM) process based on Flexible and Interactive Tradeoff (FITradeoff), in order to deal with partial preference information. An emphasis on the conceptual decision process is given. A short view of a web-based Group Decision Support System (FITradeoff-GDSS) is given, representing a practical decision tool for aiding the solution of problems of group decision with multiple criteria. The system uses only partial and minimum preference information from different DMs, requiring less cognitive effort in a more confident way. The preference modeling process combines both decomposition and holistic evaluation. The decision process can be implemented with separate or simultaneous elicitation processes for the group of DMs. In both processes the analyst and DMs can concentrate the analysis on the potential optimal alternatives of DM and also the information of alternative rankings for each DM. Several visualizations with partial results are provided by the FITradeoff-GDSS, at each step of the preference modeling process. This allows DMs can reach a final agreement without going further in the elicitation process. Also, analytical aggregation tools can be provided considering both cardinal and ordinal aggregation approaches.

2 - Multicriteria Group Decision Process with the FITradeoff Group Decision Support System (FITradeoff-Gdss)

Wagner Farias Gouveia, Federal University of Pernambuco, Recife, Brazil, Eduarda Frej, Adiel de Almeida

This work aims to present the FITradeoff Group Decision Support System (FITradeoff-GDSS), which operationalizes the group decision process with the FITradeoff method. FITradeoff-GDSS is an interactive web-based system with several flexibility features for users to take advantage of. The preferences elicitation process of group members may be conducted either simultaneously or independently. Based on individual results analysis, there are multiple ways to address the group decision problem and reach a final solution. This can be done considering a participatory process, in which results can be analyzed and discussed considering different visualization tools provided by the GDSS. Alternatively, if no agreement is reached based on this participatory process, different aggregation tools available in the system may be applied to find a compromise solution for the group. The preferences modeling process of group members in FITradeoff-GDSS should be guided by an analyst, who must aid the DMs in the whole process. This work will present an overall description of the system, raising all flexibility features and tools applied to facilitate the group decision process.

3 - A Negotiation Model for Conflict Resolution in A Brazilian Watershed

Danielle Costa Morais, Universidade Federal de Pernambuco, Recife, Brazil, Caio Vinicius Araujo Ferreira Gomes

Water resources management involves complex processes with multiple stakeholders whose interests often conflict, leading to disputes that may manifest in various forms, such as access to water, availability, resource quality, and prioritization of use. In this context, this study proposes a negotiation model for mediating conflicts within Watershed Committees. To demonstrate the applicability of the proposed negotiation model, a simulation was conducted in the Salgado River sub-basin, located in the semi-arid region of northeastern Brazil, considering a bilateral conflict between water users and the managing authority. The defined issues included environmental education, waste management, sustainable agricultural practices, fisheries control, safe water access, and the monitoring of water use. The negotiation was structured into three stages: (i) preference elicitation, conducted using the FITradeoff method, which generates a ranking of option sets; (ii) offer exchange, carried out through successive rounds based on the obtained rankings, allowing negotiators to formulate proposals and evaluate counterproposals; and (iii) agreement definition, consolidating a compromise solution between the parties. The rankings were compared, confirming that the agreement constituted a Pareto-optimal compromise, as no alternative would yield better results for one party without compromising the interests of the other. This study highlights the proposed model as a decision support tool for negotiation in participatory management contexts, with potential applicability to a broad range of conflicts in river basins. The use of the proposed model promotes greater transparency, encourages constructive dialogue, ensures a balance of stakeholder interests, and reinforces the legitimacy of collaborative decision process.

4 - A Multicriteria Group Decision Model for Managing Risk in Urban Floods

Lucas da Silva, Universidade Federal de Pernambuco, Recife, Brazil, Danielle Morais, Marcelo Alencar, Rodrigo Ferreira, Adiel de Almeida

Fostering resilient societies against climate-driven extreme events is challenging due to uncertain and conflicting urban strategies. From a multidimensional perspective, this study undertakes a group-based decision model grounded in a multicriteria framework that integrates human, environmental, and economic criteria to evaluate urban floods under risk and uncertainty. The model accounts for bringing together decision-makers who combine their preferences and knowledge to enhance problem modeling in risky situations in a changing climate. A numerical case study supported by graphical and simulation techniques offers a comprehensive analysis, showcasing how the approach can strengthen collaborative urban adaptation strategies in effective and applicable ways.

1 - Distributional Adversarial Attacks and Training in Deep Hedging

Guangyi He, Imperial College London, London, United Kingdom

We study the robustness of classical deep hedging strategies under distributional shifts by leveraging the concept of adversarial attacks. We first demonstrate that standard deep hedging models are highly vulnerable to small perturbations in the input distribution, resulting in significant performance degradation. Motivated by this, we propose an adversarial training framework tailored to increase the robustness of deep hedging strategies. Our approach extends pointwise adversarial attacks to the distributional setting and introduces a computationally tractable reformulation of the adversarial optimization problem over a Wasserstein ball. This enables the efficient training of hedging strategies that are resilient to distributional perturbations. Through extensive numerical experiments, we show that adversarially trained deep hedging strategies consistently outperform their classical counterparts in terms of out-of-sample performance and resilience to model misspecification. Our findings establish a practical and effective framework for robust deep hedging under realistic market uncertainties.

2 - Diffusion Factor Models: Generating High-Dimensional Returns with Factor Structures

Yumin Xu, Peking University, Beijing, China, People's Republic of

We introduce a diffusion factor model that integrates latent factor structures into generative diffusion processes to address high dimensionality and data scarcity in financial simulation. By decomposing the score function via time-varying orthogonal projections, we design neural architectures that exploit the low-dimensional factor structure of asset returns. Our analysis provides statistical guarantees depending only on the intrinsic factor dimension k , not the number of assets d , overcoming classical dimension-dependent limits. Numerical studies show superior subspace recovery in small data regimes, and empirical tests highlight economic value in portfolio construction. This work offers the first theoretical integration of factor models with diffusion processes, establishing a principled framework for scalable financial scenario generation.

3 - Arbitrage on Decentralized Exchanges

Yutian Zhou, The Chinese University of Hong Kong, Hong Kong, Hong Kong

Decentralized exchanges (DEXs) are alternative venues to centralized exchanges (CEXs) for trading cryptocurrencies and have become increasingly popular. An arbitrage opportunity arises when the exchange rate of two cryptocurrencies in a DEX differs from that in a CEX. Arbitrageurs can then trade on the DEX and CEX to make a profit. Trading on the DEX incurs a gas fee, which determines the priority of the trade being executed. We study a gas-fee competition game between two arbitrageurs who maximize their expected profit from trading. We derive the unique symmetric mixed Nash equilibrium and find that (i) the arbitrageurs may choose not to trade when the arbitrage opportunity and liquidity is small; (ii) the probability of the arbitrageurs choosing a higher gas fee is lower; (iii) the arbitrageurs pay a higher gas fee and trade more when the arbitrage opportunity becomes larger and when liquidity becomes higher; (iv) the arbitrageurs' expected profit could increase with arbitrage opportunity and liquidity. The above findings are consistent with our empirical study.

4 - The Paradox of Just-in-Time Liquidity in Decentralized Exchanges

Brian Zhu, Columbia University, New York, NY, United States

Passive liquidity providers (PLPs) in automated market makers face inevitable rent extraction from arbitrageurs, but remain profitable when trading fees outweigh positional losses. We show that just-in-time (JIT) liquidity enhances PLP profitability if order flow scales sufficiently with market depth, but otherwise displaces PLPs. To prevent this displacement, we propose a two-tiered fee structure that transfers a portion of JIT LP fee revenue to PLPs. Empirically, we find that JIT LPs are informed, and leveraging the launch of MEV-Boost as a shock to the block production process, we demonstrate that JIT liquidity complements, rather than crowds out, PLPs in practice.

Office of Naval Research Program Review 2

Invited Session

ONR

Chair: David Phillips, Office of Naval Research, Arlington, VA, United States

1 - Global Guarantees for Robust Matrix Factorization: Promises of Nonconvex Formulations

Salar Fattahi, University of Michigan, Ann Arbor, MI, United States

Low-rank matrix factorization is inherently a nonconvex optimization problem. The classical approach to solving such problems involves convex relaxation techniques, often enhanced with various regularization terms. While theoretically appealing, these convex methods are rarely used in practice due to their high computational cost. Instead, practitioners typically tackle the original nonconvex formulation using simple local search algorithms, such as (sub-)gradient methods. In this talk, we explore promises of nonconvex formulations, with a focus on their optimization landscape, the design of provably convergent and efficient algorithms, and their robustness to noise and model misspecification.

2 - Semidefinite Relaxations for Dynamic Combinatorial Optimization

Alejandro Toriello, Georgia Tech ISyE, Atlanta, GA, United States, Diego Cifuentes

Review for the project "Semidefinite Relaxations for Dynamic Combinatorial Optimization", sponsored by the Office of Naval Research.

3 - Boosting Convergence and Performance of Minimax Algorithms Through Acceleration and Stochastic Methods

Quoc Tran-Dinh, University of North Carolina-Chapel Hill, Chapel Hill, NC, United States

Minimax optimization plays a pivotal role in various areas, including robust optimization, game theory, and machine learning. In recent years, numerous high-impact applications — such as adversarial training, distributionally robust optimization, reinforcement learning, and online learning — have been formulated as minimax problems, further highlighting the appeal of this research area. Our ONR project (N00014-23-1-2588) was established to investigate these problems through the lens of the optimality tracking principle, in conjunction with contemporary optimization techniques. In this talk, the PI will present recent results from this ONR project. We begin by recasting the optimality condition of minimax problems as a generalized equation or root-finding problem involving structured operators. Building on this formulation, we introduce several new algorithms that leverage both modern optimization strategies and innovative ideas such as acceleration, randomization, and stochastic techniques. We also provide a novel convergence analysis based on Lyapunov functions, which leads to new convergence guarantees that extend beyond those found in current literature. Finally, we demonstrate practical applications in statistical learning and federated learning and outline future research tasks and potential applications stemming from the results of this project.

4 - Randomized Optimization Algorithms for Large-Scale Data Systems

Clifford Stein, Columbia University, New York, NY, United States

First we address the fully-dynamic carpooling problem with recourse: Edges arrive and depart online from a graph G nodes according to an adaptive adversary. Our goal is to maintain an orientation H of G that keeps the discrepancy, defined as

$$\max_v |\text{outdegree}_H(v) - \text{indegree}_H(v)|,$$

small at all times. We present a simple algorithm and analysis for this problem with recourse based on cycles, and a reduction to low girth graphs.

Next, we address point-to-point packet routing in undirected networks, which is the most important communication primitive in most networks. The main result proves the existence of routing tables that guarantee a polylog-competitive completion-time series deterministically. In any undirected network it is possible to give each node simple stateless deterministic local forwarding rules, such that, any adversarially chosen set of packets are delivered as fast as possible, up to polylog factors. All previous routing strategies crucially required randomization for both route selection and packet scheduling. The core technical contribution of this work is a new local packet scheduling result of independent interest.

1 - AI as A Framing Tool: Investigating the Influence of Generative Summary on Review Generation Through A Natural Experiment

Rui QIN, The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Zhaoyang YU, Katherine Feng

The integration of generative AI into digital platforms has introduced AI-generated summary (AIGS) of online reviews as a novel interface for presenting consumer opinions, potentially altering how consumers process information and articulate their own reviews. This paper empirically investigates the impact of AIGS on consumers' cognitive processing and review generation, with a particular focus on the multidimensional cue the summary conveys. Leveraging a cross-platform difference-in-differences (DID) model, we compare consumer review generation on Tripadvisor, where AIGS was introduced, with Booking, which did not adopt this feature. Our analysis shows that AIGS significantly influences both the numerical ratings and the textual content of consumer reviews. Following the introduction of AIGS, consumers tend to provide less extreme ratings and write reviews using simpler lexicon and syntax. Mediation analysis suggests that the multidimensional nature of AIGS broadens consumers' evaluative scope during cognitive processing, which in turn shapes how they formulate and express their opinions. Our study contributes to a growing literature on human-AI interaction by revealing how AIGS can act as a cognitive framing tool in digital content creation. The findings offer actionable insights for platform designers seeking to guide user-generated content and cultivate more balanced and informative online reviews through AI-driven interventions.

2 - Gov-Rag: a Retrieval-Augmented Generation Framework for Enhancing E-Government Services

Miao Yu, The University of Hong Kong, Hong Kong, Hong Kong, Hailiang Chen

The rapid evolution of Large Language Models (LLMs) has opened new opportunities for applying AI in high-stakes domains. However, deploying LLMs involves challenges like outdated training data, limited explainability, and reliability issues due to hallucinations. This study introduces Gov-RAG, a novel Retrieval-Augmented Generation framework, specifically tailored to address the unique demands of e-government applications. Grounded in trust in automation theory and domain-specific practical adaptation needs, the Gov-RAG framework achieves five key goals: (1) In-depth domain knowledge, (2) Factual accuracy in sensitive domains, (3) Human-centered explainability, (4) Low-cost real-time updates, and (5) Hallucination reduction. The framework incorporates a real-time updated comprehensive dataset, aggregating national laws, regulations, and government policies. To enhance retrieval precision, Gov-RAG combines dense and sparse vector retrieval with inverted index full-text retrieval and applies domain-specific hierarchical slicing. We also develop a fact-based evaluation framework to measure hallucinations across different LLM architectures, an aspect that was not properly measured in prior work. Rigorous computational experiments show that while fine-tuning improves stylistic alignment with standard answers, it also increases hallucination. Gov-RAG can improve factual consistency and reduce contradictions, consistently outperforming base LLMs and alternative frameworks in governmental applications. Furthermore, RAG with fine-tuned LLMs exhibits degraded performance in answering questions that require historical knowledge. Gov-RAG exhibits balanced capabilities across different test datasets. Online experiments with real citizens further validate the feasibility and impact of Gov-RAG on user performance, user perceptions, and user behaviors. Results indicate significant improvements in task performance, user-perceived explainability, and efficiency during engagement compared to base LLMs.

3 - The Economics of on-Premise LLMs

Jiaqi Shi, University at Buffalo, Buffalo, NY, United States, Zhoupeng Zhang, Shaojie Tang

Large Language Models (LLMs) like ChatGPT and DeepSeek have surged in capability and popularity, enabling diverse applications from automated customer service to content generation. LLM users now face a critical choice between utilizing cloud services and running on-premise models. This decision carries significant implications for cost, data privacy, and performance. Simultaneously, LLM service providers face the challenge of determining if and when to allow users to deploy models locally. Our study analyzes how LLM providers' choices regarding service models impact their revenue and the corresponding consumer behavior.

4 - Voice Versus Text? An Empirical Analysis on the Impact of Physicians' Voice Messages in Online Medical Consultations

Shengjun Mao, The University of Hong Kong, Hong Kong, Hong Kong

While Online Medical Consultation (OMC) platforms offer patients convenient and accessible healthcare services, challenges remain in ensuring effective communication between physicians and patients. Several OMC platforms provide physicians with a voice reply function, enabling them to send voice messages during consultations. This study aims to examine the effectiveness of such an IT-enabled function. We integrate media synchronicity theory (MST) and social support theory (SST) to develop a conceptual framework, highlighting how different media with various capabilities influence OMC performance by enabling physicians to convey specific components of social support. Specifically, we analyze data from a leading OMC platform in China to assess the impact of physicians' adoption of voice messages on OMC outcomes. The empirical results show that when physicians use voice messages to respond to patients, patients are more likely to report higher satisfaction and perceive the consultation as more helpful. To explore the underlying mechanisms, we develop advanced deep learning models to extract key factors of emotional support and informational support within OMC interactions. By conducting moderation analyses, we find that voice messages are particularly effective in conveying emotional support components like empathy and affirmation, as well as concrete informational support, which enhances the effects of voice-message use on OMC performance. Our findings suggest that healthcare stakeholders can strategically leverage the voice message feature to improve online consultation outcomes.

1 - Machine Unlearning: is One Newton Step Enough?

Haolin Zou, Columbia University, New York, NY, United States, Arnab Auddy, YongChan Kwon, Kamiar Rahnema Rad, Arian Maleki

Machine unlearning focuses on the computationally efficient removal of specific training data from trained models, ensuring that the influence of forgotten data is effectively eliminated without the need for full retraining. Despite advances in low-dimensional settings, where the number of parameters p is much smaller than the sample size n , extending similar theoretical guarantees to high-dimensional regimes remains challenging.

We study an unlearning algorithm that starts from the original model parameters and performs a theory-guided sequence of Newton steps $(T \in \{1, 2\})$. After this update, carefully scaled isotropic Laplacian noise is added to the estimate to ensure that any (potential) residual influence of forget data is completely removed.

We show that when both $(n, p \rightarrow \infty)$ with a fixed ratio (n/p) , significant theoretical and computational obstacles arise due to the interplay between the complexity of the model and the finite signal-to-noise ratio. Finally, we show that, unlike in low-dimensional settings, a single Newton step is insufficient for effective unlearning in high-dimensional problems---however, two steps are enough to achieve the desired certifiability. We provide numerical experiments to support the theoretical claims of the paper.

2 - Improved Complexity for Nonconvex Optimization: Two-Level Online Learning with Quasi-Newton Methods

Ruichen Jiang, University of Texas at Austin, Austin, TX, United States, Aryan Mokhtari, Francisco Patitucci

A fundamental problem in optimization is finding an ϵ -first-order stationary point of a smooth nonconvex function using only gradient information. The best-known gradient complexity for this task, assuming both the gradient and Hessian of the objective function are Lipschitz continuous, is $O(\epsilon^{-1.75})$. In this talk, I will present a new method with a gradient complexity of $O(d^{0.25}\epsilon^{-1.625})$, where d is the problem dimension, yielding an improvement when $d = O(\epsilon^{-0.5})$.

Our key idea is to design a quasi-Newton method that operates through two levels of online learning. Specifically, we first reformulate the task of finding a stationary point for a nonconvex problem as minimizing the regret in an online convex optimization problem, where the loss is determined by the gradient of the objective function. Then, we introduce a novel optimistic quasi-Newton method to solve this online learning problem, with the Hessian approximation update itself framed as an online learning problem in the space of matrices. Beyond improving the known complexity bounds, our result provides the first guarantee that quasi-Newton methods can outperform gradient descent-type methods in nonconvex optimization.

3 - The Power of Adaptivity in SGD

Matthew Faw, Georgia Institute of Technology, Atlanta, GA, United States

We study convergence rates of AdaGrad-Norm as an exemplar of adaptive stochastic gradient descent (SGD) methods, which adjust their step sizes based on observed stochastic gradients, for minimizing non-convex, smooth objectives. Despite their popularity, the analysis of adaptive SGD lags behind that of non-adaptive methods in this setting. Specifically, all prior studies rely on some subset of the following assumptions which are unnecessary in the analysis of fixed step-size SGD: (i) uniformly bounded gradient norms, (ii) uniformly bounded stochastic gradient variance (or even noise support), (iii) conditional independence between the step size and stochastic gradient. In this work, we show that AdaGrad-Norm exhibits an order optimal (up to polylogarithmic factors) convergence rate, scaling inversely with the square-root of T after T iterations, under the same standard assumptions as a well-tuned fixed step-size SGD (unbounded gradient norms and affine noise variance scaling). We also go beyond the standard smoothness assumption, proving similar results for (L_0, L_1) -smooth (non-convex) functions (where the norm of the Hessian can scale affinely with the norm of the gradient, e.g., the exponential function). This is the first rate of convergence for any algorithm in this smoothness and noise regime, even for the special case of uniformly-bounded variance.

4 - Stochastic Gradient Methods Without Replacement in Finite-Sum Optimization

Trang Tran, Lehigh University, Bethlehem, PA, United States, Lam Nguyen, Katya Scheinberg

We consider the finite-sum optimization problem, which is important in machine learning, where the objective function is an average of loss functions over many data samples. Stochastic gradient descent and its momentum variants are effective and scalable for this problem. While the theoretical analysis for these methods often relies on sampling with replacement, most practical machine learning libraries use sampling without replacement (shuffling sampling) for the update sequence.

In this talk, we first briefly discuss some theoretical advantages of shuffling sampling in stochastic gradient methods. Then, we introduce Nesterov Accelerated Shuffling Gradient (NASG) algorithm for convex finite-sum minimization, which integrates Nesterov's acceleration momentum with shuffling sampling. This algorithm has a convergence rate of $O(1/T)$ where T is the number of data passes, which is better than any other shuffling gradient methods in a general convex setting. Finally, we discuss a theoretical connection with multi-objective optimization.

1 - From Views to Value: a Multimodal Analysis of Video Engagement and Learning Outcomes in Online Education

Yi-Yun Chu, Carnegie Mellon University, Pittsburgh, PA, United States

As digital learning platforms increasingly become the primary interface between learners and educational content, understanding how platform design shapes engagement and performance is critical. This study investigates how video structure, cognitive load, instructor characteristics, and learner behavior interact to influence engagement and academic outcomes in online learning environments. Using a large-scale, cross-subject dataset, we examine the nuanced relationship between cognitive demand and learning efficacy, identifying an optimal challenge zone where moderate cognitive load maximizes video completion and performance. To support this analysis, we construct a multimodal cognitive load measurement framework that captures moment-to-moment learner difficulty using interaction patterns and video structural features. We find that video structure, ranging from introductory motivational segments to core concept delivery and advanced, example-driven dense presentations, plays a key role in mediating these effects. Moreover, instructor attributes and learner replay behaviors show dynamic patterns of engagement, highlighting the potential for real-time, AI-driven interventions to support adaptive scaffolding. Overall, our findings offer actionable insights for platform designers and educators, advocating for dynamic, modular video content and behavior-aware personalization to enhance learning outcomes at scale.

2 - Quantifying the Adoption of LLM-Assisted Writing in Society: Evidence from Science, Business, and Public Discourse**Hancheng Cao, Emory University, Atlanta, GA, United States**

Generative AI tools like ChatGPT are reshaping how people write across many parts of society, yet their real-world adoption has been difficult to measure. In this talk, I present a statistical framework for estimating the presence of LLM-assisted writing across large-scale corpora. Applying this approach to diverse datasets—including scientific peer reviews, academic manuscripts, job posts, consumer complaints, and international press releases—we uncover clear and accelerating patterns of LLM adoption. These trends vary across domains, timeframes, and organizational contexts, offering insight into how generative AI is being integrated into high-stakes communication.

3 - Creative Markets in the Age of Generative AI: Strategic Shifts and Labor Market Health**Eric Zhou, Boston University, Boston, MA, United States**

The rise of generative artificial intelligence (AI) has sparked significant debate about its impact on creative labor markets, echoing concerns raised nearly 200 years ago with the advent of photography. While early photographic technologies displaced traditional portraiture forms, they also spurred artistic innovation, as painters embraced abstraction and new approaches to human expression. Today, generative AI poses a similar challenge but at an unprecedented scale, raising concerns about labor displacement, intellectual property, and the future of human creativity. This paper investigates how creators respond to competitive pressures and ethical concerns associated with generative AI by adopting, protesting, or opting out of AI training systems and the long-term implications of these strategic shifts on the health and composition of creative markets. We conduct artist- and artifact-level analyses using large-scale data from a creative labor market platform to understand strategic responses to both the introduction of AI and protections offered by the platform against AI. We investigate to what extent these strategic shifts impact the overall artist and artwork composition within the broader creative labor market and its implications on the long-term health of such markets.

4 - AI Regulation in the US: A Descriptive Analysis**Hemant Bhargava, University of California, Davis, CA, United States**

This work will be discussing trends in AI regulation among the 50 state legislatures in the US, including key topics, factors that affect success (enactment) vs failure, overlap and sequencing across states, and intensity of regulation vs various state-specific factors.

1 - Strategic Timing in Crowdfunding: Effect of Competition on Project Launch Decisions**Shaolin Pu, The University of Kansas, School of Business, Lawrence, KS, United States, Karthik Srinivasan, Ben Sherwood, Arvind Tripathi**

Launching a reward-based crowdfunding (RBC) campaign mirrors the complexity of starting a small venture, requiring more than a compelling idea—it demands strategic timing amid competition. While prior research has focused on storytelling and project presentation, little is known about how competitive pressure shapes creators' launch decisions. This study addresses that gap by examining whether the presence of mega (high-performing) and ordinary (newly launched) competitors influences creators' timing strategies and campaign outcomes. Using data from 184,537 Kickstarter projects (2014–2022), we analyze creators' day-level launch behavior and its effect on pledged amounts. Our findings show that creators strategically adjust their launch timing not only to benefit from the positive network effects of high-profile competitors, but also to avoid periods of intense competition that could overshadow their campaigns, and that such avoidance positively impacts funding performance. These insights highlight the importance of competition-aware timing strategies and offer practical implications for campaign planning and platform management in RBC ecosystems.

2 - Creditability and Risk of Explanations for AI Model's Predictions**Amir Asrzd, University of Massachusetts Lowell, Lowell, MA, United States**

This talk presents a framework for generating credible and risk-sensitive counterfactual explanations for machine learning (ML) model predictions. While ML and AI models often achieve high predictive accuracy, their black-box nature makes them difficult to interpret, posing significant challenges for adoption in high-stakes domains. Explainable AI (XAI) aims to address this issue by producing explanations that are meaningful to users. However, most existing XAI methods assume that model predictions are correct, leading to potentially misleading or incomplete explanations, especially when predictions are uncertain or unreliable.

This research tackles two fundamental problems in XAI: the credibility of uncertain predictions and the risk of misleading explanations. We propose new credibility measures to detect and flag unreliable predictions, and develop a novel method for generating two types of counterfactual explanations: robust counterfactuals that reduce the risk of weak or unstable explanations, and vigilant counterfactuals that sensitively detect harmful or undesirable changes.

The method is validated empirically using real-world data, demonstrating its effectiveness in improving the trustworthiness of AI-assisted decision-making. This work contributes to the development of more transparent and responsible AI systems, particularly in environments where prediction errors can have serious consequences.

3 - Human-Centered AI/ML Systems: Bridging Research and Industry Applications in Healthcare and Technology**Grace Babalola, Binghamton University, Binghamton, NY, United States**

My work showcases a comprehensive research program that integrates human factors engineering and data science with advanced AI/ML systems to optimize decision-making in complex, high-stakes environments. My work demonstrates how human-centered design principles can enhance AI system effectiveness across healthcare, web security, and e-commerce domains.

At Microsoft, I developed LLM-powered knowledge base chatbots using Azure OpenAI and RAG architectures for performance improvements through Teams integration and automated data processing. I also created heuristic algorithms for phishing detection that improved ML model performance through automated ground truth data generation.

My Amazon research focused on augmented analytics for natural language processing, where I built ensemble ML systems and NER pipelines using spaCy to streamline developer workflows and extract business insights from device hardware/software datasets.

At Excellus Blue Cross Blue Shield, I developed predictive models for chronic condition risk assessment and member sentiment analysis, optimizing KPIs and improving service delivery for 5,000+ members through interactive R Shiny applications.

My doctoral dissertation research addresses critical gaps in healthcare decision-making by developing AI-powered applications that reduce nursing cognitive load while maintaining human-centered design principles. Through comprehensive user research across 8 U.S. states, I identified workflow challenges and designed evidence-based decision support systems that facilitate peer collaboration and accelerate clinical decision-making.

This integrated approach demonstrates how rigorous human factors research can inform practical AI implementations, creating systems that augment rather than replace human expertise across diverse industry applications.

1 - Novel Experimental Design and Analysis Method for Solver Selection, Blockchain Design and Educational Games

Ramiro Rodriguez Buno, The Ohio State University, Columbus, OH, United States, Theodore Allen

We developed an experimental method to perform hyper-parameter tuning for new optimization problems with shared, nested and random factors with a large number of runs. We aim to optimize solver engines with applications in airline operations and compare the performance of the solvers. Initially, the experiments were based on standard library MILP problems, later, we developed our methodology for specific problems in the airline industry, to contrast the difference in results.

For a second problem, we create a design and analysis method to tune private blockchains models to different environments for industrial applications and manufacturing. We started comparing different blockchain simulators, protocols (block, transactions, nodes parameters) and analyze the main relevant outputs (transaction throughput, blockchain ledger, block mined, stale blocks, rewards gained by each miner) to select the best parameter set configuration. We study the robustness of the protocol and implications for cybersecurity.

In a third matter, we develop game-based methods for teaching experimentation and optimization in manufacturing and systems operations management. The idea is to maximize the benefits of a good DOE planning and strategy selection, comparing to the experimentation information improvements if the strategy selected is doing a lot of trial-and-errors or One-Factor-At-a-Time (OFAT).

2 - Personalized Policy Learning Through Discrete Experimentation: Theory and Empirical Evidence

Zhiqi Zhang, Washington University in St. Louis, St. Louis, MO, United States, Zhiyu Zeng, Ruohan Zhan, Dennis Zhang

Randomized Controlled Trials (RCTs), or A/B testing, have become the gold standard for optimizing various operational policies on online platforms. However, RCTs on these platforms typically cover a limited number of discrete treatment levels, while the platforms increasingly face complex operational challenges involving optimizing continuous variables, such as pricing and incentive programs. The current industry practice involves discretizing these continuous decision variables into several treatment levels and selecting the optimal discrete treatment level. This approach, however, often leads to suboptimal decisions as it cannot accurately extrapolate performance for untested treatment levels and fails to account for complex interactions between treatment effects and user characteristics. This study addresses these limitations by developing a theoretically solid and empirically verified framework to learn personalized continuous policies based on high-dimensional user characteristics, using observations from an RCT with only a discrete set of treatment levels. Specifically, we introduce a deep learning for policy targeting (DLPT) framework that includes both personalized policy value estimation and personalized policy learning. We prove that our policy value estimators are asymptotically unbiased and consistent, and the learned policy achieves a square root of n regret bound. We empirically validate our methods in collaboration with a leading social media platform to optimize incentive levels for content creation. Results demonstrate that our DLPT framework significantly outperforms existing benchmarks, achieving substantial improvements in both evaluating the value of policies for each user group and identifying the optimal personalized policy.

3 - Efficient Active Learning Strategies for Computer Experiments

Difan Song, Georgia Institute of Technology, Atlanta, GA, United States, Roshan Joseph

Active learning in computer experiments aims at allocating resources in an intelligent manner based on the already observed data to satisfy certain objectives such as emulating or optimizing a computationally expensive function. There are two main ingredients for active learning: an initial experimental design, which helps to approximately learn the function, and a surrogate modeling technique, which provides a prediction of the output along with its uncertainty estimates. Space-filling designs are commonly used as initial designs and Gaussian processes for surrogate modeling. This article aims at improving the active learning procedure by proposing a new type of initial design and a new correlation function for the Gaussian process. The ideas behind them are known in other fields, such as in sensitivity analysis or in kernel theory, but they never seem to have been used for active learning in computer experiments. We show that they provide substantial improvement to the state-of-the-art methods for both emulation and optimization. We support our findings through theory and simulations, and a real experiment on the vapor-phase infiltration process.

4 - Regression Adjustment for Average Treatment Effect in Finite Population Randomized Controlled Trials

Mehrdad Ghadiri, MIT, Cambridge, MA, United States, Ali Jadbabaie, Alberto Abadie, Mahyar Jafarinodeh

The design and analysis of randomized experiments are fundamental to many fields, from the physical and social sciences to industrial applications. Regression adjustment is a widely used technique for leveraging auxiliary covariate information to reduce the variance of experimental estimates. Although a large body of work in statistics and econometrics studies various regression-adjustment methods and their asymptotic properties, relatively little attention has been paid to finite-population settings with non-asymptotic accuracy guarantees.

In this talk, we consider the estimation of the average treatment effect (ATE) in finite population randomized controlled trials. We introduce unbiased ATE estimators based on both simple and complete randomization combined with regression adjustment, and we derive non-asymptotic bounds on their variance, concentration, and confidence intervals. Moreover, we discuss connections between our estimators and both classic and modern methods in experimental design and regression adjustment, and we present numerical comparisons demonstrating that our estimators outperform existing approaches in practice.

High-dimensional Data Analysis I

Job Market Showcase

Job Market Showcase

Chair: Linfeng Song, North Carolina State University, Raleigh, NC, 27606, United States

1 - AI-Driven Analysis and Optimization of Systems with High-Dimensional Sensing Data

Mohammad Bisheh, Georgia Institute of Technology, Atlanta, GA, United States

Modern manufacturing and health-monitoring systems generate high-dimensional, noisy, and often incomplete sensor streams, and transforming these raw data into actionable insights requires methods that are both statistically rigorous and computationally scalable. This presentation offers an integrated statistical-learning framework, rooted in data science and advanced manufacturing, to address key challenges in additive manufacturing (AM), 3D printing, and multivariate anomaly detection across diverse industrial and biomedical settings. At its core is a robust functional tensor-decomposition (RFTD) algorithm that treats multichannel time-series data as time-

indexed tensors, enforces spatio-temporal smoothness, and iteratively separates each tensor into a low-rank “true process” component and a sparse “anomaly” component, even under asynchronous sampling and missing values, via proximal alternating minimization. Complementing RFTD, an adaptive feature-extraction pipeline combines Daubechies wavelet packets with short-time Fourier transforms to yield shift-invariant, noise-resilient descriptors; coupled with isolation forests and local outlier factors, this pipeline dramatically improves fault isolation over kernel-PCA baselines. To reduce experimental burden in metal and polymer AM, a transfer-learning scheme propagates layer-wise printability knowledge across materials, while manifold learning on electron-backscatter diffraction images clusters grains by morphology and orientation, enabling microstructure-aware monitoring with minimal labeling. Beyond manufacturing, applying RFTD-derived tensor graphs to resting-state fMRI uncovers time-varying connectivity patterns associated with ADHD and ASD, illustrating the method’s versatility for biomedical signal analysis. Collectively, these contributions deliver a scalable AI toolkit for real-time quality assurance, process optimization, and anomaly detection, advancing the reliability, efficiency, and adaptive intelligence of next-generation smart-manufacturing and health-monitoring ecosystems.

2 - Continuous-Time Modeling of Complex Operational Systems with Neural Differential Equations

YongKyung Oh, UCLA, Los Angeles, CA, United States

Many critical operational systems, from patient health trajectories in healthcare to asset movements in logistics, are inherently dynamic and generate complex, irregularly-sampled time series data. Effectively modeling these continuous-time processes to support robust and timely decision-making remains a significant challenge for conventional discrete-time analytical methods, which can struggle with asynchronous observations and underlying system dynamics. My research direction focuses on advancing and applying Neural Differential Equations (NDEs) and related continuous-time modeling frameworks to overcome these limitations. This approach allows for a more natural and powerful representation of systems that evolve continuously, directly handling irregularly-sampled data and offering the potential to uncover the governing dynamics with greater fidelity. The core of this research involves developing novel NDE-based architectures and robust learning algorithms tailored for operational data.

Beyond methodological innovation, a key objective is to ensure these advanced continuous-time models are robust, interpretable, and deployable in critical operational settings, addressing challenges like data shifts. The ultimate aim is to leverage these NDE-based modeling capabilities to significantly enhance forecasting, real-time anomaly detection, and control strategies. Applications span improving dynamic risk assessment in healthcare, optimizing traffic flow in intelligent transportation systems, and increasing the efficiency of supply chain logistics, leading to more adaptive, insightful, and effective decision support systems. This continuous-time modeling paradigm offers new avenues for tackling previously intractable challenges in the analysis and control of dynamic operational environments.

3 - An Explainable Neural Network Framework for Multi-Sensor Prognostics

Linfeng Song, North Carolina State University, Raleigh, NC, United States

Accurate prediction of failure times is critical for the effective maintenance and risk management of complex engineering systems. This study proposes an explainable neural network (XNN) framework for multi-sensor prognostics that enables interpretable failure time prediction. The framework integrates deep learning-based regression with feature attribution techniques to identify the most informative sensors contributing to the remaining useful life (RUL) estimation. Through simulated experiments, we demonstrate that the proposed model achieves competitive prediction accuracy while providing transparent insights into sensor relevance. By enhancing interpretability without sacrificing performance, this work contributes to building trustworthy, data-driven prognostic tools in industrial applications.

4 - Theoretical Analysis for Optimal Design of An Online Monitoring and Sampling Scheme Under Partial Observations

Dongmin Li, Georgia Institute of Technology, Atlanta, GA, United States, Xiaochen Xian

High-dimensional streaming data is collected in a wide range of applications, such as advanced manufacturing and environmental monitoring. However, practical constraints such as limited sensors, transmission bandwidth, and data storage capacity, restrict the ability to observe all variables of interest at each data collection time for online monitoring. Although adaptive sampling strategies have been proposed that are integrated into monitoring schemes for quick anomaly detection, the theoretical analysis of detection performance for optimal design in practical settings has not been addressed. While few studies provide upper bounds for the average detection delay, the bounds are either asymptotic or excessively large, failing to provide valuable guidance on parameter design for optimal detection performance in practical applications. To fill this gap, we propose a holistic monitoring-based probabilistic sampling framework under partial observations and theoretically analyze the average detection delay to inform optimal design. By leveraging the sampling probabilities of variables, which are explicit functions of monitoring statistics, we derive formulas for practical average detection delay as functions of design parameters and system settings, such as the number of sampled variables and total variables in the system. These theoretical results enable the determination of the number of sampled variables and parameter settings to achieve optimal detection performance while satisfying false alarm requirements and considering practical resource constraints such as sampling costs. Simulation studies across various parameters and system settings validate the effectiveness of the theoretical results, demonstrating significant practical value for optimal performance design.

Chair: Varun Suriyanarayana, Cornell University, Ithaca, NY, United States

1 - 3D-Printing for Supply Chain Resilience

Ziyu He, University of Southern California, Los Angeles, CA, United States, Vishal Gupta, Nick Vyas

Most strategies for mitigating supply chain disruptions require upfront, dedicated investments for each supplier, making them impractical for large, disaggregated supply chains. We study using 3D printing (3DP) as a flexible, backup resource that can support any disrupted supplier. 3DP has traditionally been rejected as a viable resilience strategy due to high per-unit production costs and limited capacity. Inspired by the “a little flexibility is enough” literature, however, we explore when and why 3DP may be a cost-effective resilience strategy and how to deploy it. We formulate an optimization model to decide which suppliers to backup with 3DP, how much 3DP capacity to procure, and how to allocate that capacity in real-time to unmet demand. The resulting mixed-binary, stochastic optimization problem is computationally challenging, even for moderate sized supply chains. Hence, we propose a novel algorithmic framework combining supermodular approximations based on Taylor series and first-order stochastic optimization to compute high-quality feasible solutions. Finally, we conduct an empirical case study based on bill-of-lading data from toy manufacturer Mattel. With cost estimates based on current technology, 3DP offer modest cost savings relative to traditional resilience strategies. However, its principal benefit is a reduction in demand shortfalls. This advantage is especially evident in larger systems with weakly correlated supplier disruptions. Resonating with the well-known “a little flexibility is enough” principle, our findings provide both analytical and empirical evidence of 3DP’s transformative potential as a strategic resilience tool for large supply chains.

2 - Designing Spare Part Supply Chains for High-Tech Products: a Life Cycle Approach Using a Bayesian Demand Model

Firat Kilci, The University of Texas at Austin, Austin, TX, United States, Genaro Gutierrez, Saurabh Bansal

Spare parts are an essential aspect of after sales service to increase product economic life, customer satisfaction, and future sales. In this study, we partner with a global computer manufacturer and examine the structure of a multi-echelon service network for spare parts in the high-tech industry over the course of their life cycle under a Bayesian demand model. High-tech components have short life cycles and are under risk of obsolescence. Overstocking these components results in high inventory holding costs in the form of depreciation and low salvage values, and understocking results in a decrease in service levels, emergency shipments costs and a possible decrease in future sales. We formulate the problem as a single-item multi-echelon Bayesian dynamic inventory problem where the aim is to decide on an inventory policy to minimize the total expected inventory management costs. We derive a near-optimal policy and provide bounds on both the policy and cost spaces. Using real data from our research partner, we use our model to derive the dynamic behavior of the structure of a multi-national supply chain network that includes 28 countries. Based on the

results, which capture the dynamic learning of demand model parameter values, we identify different dynamic behaviors corresponding to the introduction, growth, maturity and decline phase of the product life cycle. This model informs management that a near-optimal global supply chain structure is a dynamic amalgamation of country specific policies responding to their own parameters, and it helps them to implement these policies.

3 - Rethinking Fulfillment Regionalization

Nidhima Grover, Georgia Institute of Technology, Atlanta, GA, United States, Daniel Ulch, Xiaoyan Si, Yuan Li, Louis Faugère, Amitabh Sinha, Benoit Montreuil

In today's retail industry with the growing opportunity of providing delivery of goods directly to consumers, companies can store their inventory at cheaper locations away from the high demand locations of customers. This provides them with the opportunity of pooling inventory at Fulfillment Centers (FCs), storing lower levels of safety stock. Recently, retailers started decomposing their fulfillment network into smaller regions through a method called Regionalization, which provided improvements in cost and speed of fulfillment. In every region, fulfillment is prioritized from a set of FCs assigned to the region, and every FC is assigned to a single region (single mapping). In this paper, we study a variant of regionalization where we can assign FCs to more than one regions (multi-mapping). This can lead to improvements in cost and speed due to reduction in in-region distances, primarily due to the effect of inventory pooling from making an FC's inventory easily accessible to more than one region. We introduce a modeling and solution framework to design regions and assign FCs to more than one region simultaneously, using a non-linear mixed integer program. Moreover, we also introduce a novel evaluation framework where we first find the percentage of regional demand that we can fulfill from FCs assigned to a region. This helps us derive inventory allocation strategies that we further employ in a placement-fulfillment simulator, which helps us demonstrate the significance of multi-mapping compared to single mapping.

4 - New Algorithms for Joint Replenishment Incorporating Modern Considerations

Varun Suriyanarayana, Cornell University, Ithaca, NY, United States, Varun Sivasankar, Siddharth Gollapudi, David Shmoys

The joint replenishment problem (JRP) is a classical inventory management problem. We consider a natural generalization with outliers, where we are allowed to reject (that is, not service) a subset of demand points. In this paper, we are motivated by issues of fairness- if we do not serve all of the demands, we wish to “spread out the pain” in a balanced way among customers, communities, or any specified market segmentation. One approach is to constrain the rejections allowed, and to have separate bounds for each given customer. In our most general setting, we consider a set of C features, where each demand point has an associated rejection cost for each feature, and we have a given bound on the allowed rejection cost incurred in total for each feature.

We give the first constant approximation algorithms for the fairness-constrained JRP with a constant number of features; specifically, we give a 2.86-approximation algorithm in this case. Even for the special case in which we bound the total (weighted) number of outliers, this performance guarantee improves upon bounds previously known for this case. Our approach is an LP-based algorithm that splits the instance into two subinstances. One is solved by a novel iterative rounding approach and the other by pipage-based rounding.

Dynamic Programming and Reinforcement Learning

Job Market Showcase

Job Market Showcase

Chair: Imon Banerjee, Northwestern University, West Lafayette, IN, United States

1 - Multi-Agent Queueing Network: Coordination with Learning

Zhaoxuan Wei, Institute of Operations Research and Analytics, NUS, Singapore, Singapore, Andrew Lim, Hanqin Zhang

We study a coordination problem in a decentralized Jackson network with an admission decision maker and multiple service providers. The admission decision maker controls the exogenous job arrivals by dynamically setting the admission fees while the service providers decide their job-processing rates. The system is operated in a decentralized way: all agents optimize their own objective subject to their local models which may mis-specify the system components controlled by other agents. We show that the decentralized queueing network can be coordinated by the transfer mechanism solving a fixed-point equation. Under the optimal transfer mechanism, the decentralized system welfare achieves the optimal centralized system welfare. The algorithm for computing the optimal mechanism and its convergence rate are established. Furthermore, we propose a reinforcement learning (RL) algorithm for the case where each decision maker interacts with its potentially biased local generative model. Our RL algorithm is shown to converge to the optimal transfer mechanism and the sample complexity for the RL algorithm is given.

2 - Mean-Variance Portfolio Selection by Continuous-TIME Reinforcement Learning: Algorithms, Regret Analysis, and Empirical Study

Yilie Huang, Columbia University, New York, NY, United States, Yanwei Jia, Xunyu Zhou

We study continuous-time mean-variance portfolio selection in markets where stock prices are diffusion processes driven by observable factors that are also diffusion processes yet the coefficients of these processes are unknown. Based on the recently developed reinforcement learning (RL) theory for diffusion processes, we present a general data-driven RL algorithm that learns the pre-committed investment strategy directly without attempting to learn or estimate the market coefficients. For multi-stock Black-Scholes markets without factors, we further devise a baseline algorithm and prove its performance guarantee by deriving a sublinear regret bound in terms of Sharpe ratio. For performance enhancement and practical implementation, we modify the baseline algorithm and carry out an extensive empirical study to compare their performance, in terms of a host of common metrics, with a large number of widely used portfolio allocation strategies on S&P 500 constituents. The results demonstrate that the proposed continuous-time RL strategy is consistently among the best especially in a volatile bear market, and decisively outperform the model-based continuous-time counterparts by significant margins.

3 - Cost-Aware Bayesian Optimization with Adaptive Stopping via Gittins Indices

Qian Xie, Cornell University, Ithaca, NY, United States, Linda Cai, Theodore Brown, Raul Astudillo, Peter Frazier, Alexander Terenin, Ziv Scully

Hyperparameter optimization is crucial in real-world applications ranging from machine learning model training to adaptive experimentation in science, engineering, and e-commerce. These scenarios are often modeled as black-box functions, which take hyperparameters as inputs and output performance metrics. Bayesian optimization is a powerful framework for efficiently optimizing such black-box functions, especially when evaluations are expensive. However, practical considerations such as varying evaluation costs, adaptive stopping time, and observable multi-stage feedback remain under-explored in this framework.

This talk is based on two of my recent works leveraging Gittins indices, which are inherently cost-aware, stopping-aware, and feedback-aware, through connections to Pandora's Box problems and Markovian/Bayesian bandits, where the Gittins policy is Bayesian-optimal. This perspective leads to a novel acquisition function together with a tuning-free stopping rule for Bayesian optimization, supported by theoretical guarantees and validated by competitive empirical performance.

I will also briefly discuss ongoing work on large language model (LLM)-driven neural architecture search for reinforcement learning (RL) state encoding, and applications to mixed-autonomy traffic control, illustrating how my research extends beyond Bayesian optimization to tackle broader challenge in mixed-type hyperparameter and architecture optimization.

4 - Statistics on Controlled Markov Chains

Chair: Chu Chu, Huazhong University of Science and Technology, Wuhan, China, People's Republic of

1 - Unveiling NFT Price Dynamics: the Interplay of Traits, Market Behaviors, and Strategic Manipulations

Micheli Liu, Emory University, Atlanta, GA, United States, Rajiv Garg

The rapid rise of Non-Fungible Tokens (NFTs) has introduced both transformative opportunities and challenges in digital markets, particularly in terms of valuation mechanisms and trading behaviors. This study investigates the determinants of NFT valuations by interacting intrinsic NFT traits, and buyer and seller behaviors, using comprehensive data from the Bored Ape Yacht Club (BAYC) collection. Employing a combination of ordinary least squares, random forest model, fixed-effects linear regression, and cross-sectional elastic-net methodologies, we find that intrinsic visual traits significantly influence initial valuations, maintaining their relevance throughout an NFT's lifecycle. Furthermore, interaction effects between these intrinsic traits and transactional behaviors highlight that buyer and seller reputation, as well as transaction history, significantly affect NFT prices. Notably, strategic price manipulations, facilitated by prominent market actors ("whales") and complex buyer-seller interactions, emerge as critical factors influencing market dynamics. These insights enhance the understanding of NFT markets and provide a foundation for regulatory frameworks.

2 - How Do Chatbots Shape Donors' Decisions in a Fundraising Project?

Maryam Noorymotlagh, University of Texas at Arlington, Arlington, TX, United States, Samaneh Samiee, Jie Zhang

This research examines the pivotal role of chatbots in influencing donors' behavior and decisions within a nonprofit fundraising organization. The novelty lies in the fact that, unlike previous studies comparing chatbots' performance with that of human agents, this study compares the performance of different chatbots. This study employs a field experiment as its methodology.

The findings reveal that empathic chatbots, which employ cognitive and affective empathy in conversation, significantly increase donors' engagement in fundraising campaigns. Specifically, chatbots that displayed a picture of a little girl during a fundraising event while conversing with donors enhanced both the number of contributions and donor engagement.

Moreover, this research highlights the potential of designing a chatbot as a virtual assistant for a nonprofit organization. It not only reduces labor costs but also fosters sustainable donor engagement.

3 - From Waiting to Winning: Impacts of Virtual Queue Services on Local Businesses

Hyeonju Ju, Korea University, Seoul, Korea, Republic of, Eric Kwon, Jin Soo Han, Gunwoong Lee

Managing wait times is a critical challenge in service industries, directly influencing customer satisfaction and revenue. Virtual queue services have emerged as a strategic solution, allowing businesses to manage wait times efficiently through online platforms or mobile applications. Despite their growing adoption, the broader impact of these services on individual customers and local businesses remains underexplored. This study addresses this gap by examining the spillover effects of virtual queue services on customer engagement and local business performance. Utilizing advanced econometric models, the research examines the influence of virtual queue services on customer decisions to engage with local businesses. Our preliminary results empirically substantiate the pivotal role of virtual queue services in vitalizing local businesses. Our findings contribute to a deeper understanding of the interplay between technology, wait time management, and local economies, providing valuable insights for local businesses, policymakers seeking to foster a more interconnected and vibrant local business environment, and business practitioners striving to optimize efficiency through digital solutions.

4 - Dynamic and Static Item Allocation for the in-Store Front Warehouses

Chu Chu, Huazhong University of Science and Technology, Wuhan, China, People's Republic of, Shiming Deng, Wen Luo

In response to furious competition from emerging online retailers, traditional supermarkets begin leveraging their brick-and-mortar store chains by setting up small in-store front warehouses to facilitate order picking processes for online orders. In this paper, we investigate how to select products and allocate space for the in-store front warehouse under dynamic and static strategies to minimize the total order-picking workload. For the dynamic allocation problem, we formulate it as a mixed-integer programming (MIP) model, which can be decomposed into a master multi-choice knapsack problem (MCKP) and an order picking problem (OPP) as sub-problems. An exact algorithm and a heuristic that is 1/2-bounded under certain routing policies are proposed. For the static allocation problem, we construct a stochastic gradient estimator of the expected travel distance by infinitesimal perturbation analysis (IPA) and introduce a discrete Frank-Wolfe algorithm to solve it. Numerical results reveal that the logic of dynamic allocation for the in-store front warehouse is different from that for regular warehouses, and the storage location assignment for the shelf area in supermarkets greatly impact the performance of these allocation strategies. The experimental results using data from a real retailer validate the effectiveness of proposed algorithms.

Building A Level 4 A401

Industry Insights Panel - The Future of Urban Mobility in Transportation and Delivery

Invited Session

Air Transportation Section

Chair: Yuqian Dong, Walmart, Seattle, United States

1 - Urban Air, Suburban Peace: Solving the Noise Puzzle for Aerial Mobility

Laura Morejón Ramírez, Whisper Aero, Crossville, TN, United States, Mark Moore

Aerial Drone Delivery and Drone as First Responder are positioned to be significant first mover markets that experience an inflection point where scaled operations will be taking place. Already, targeted initial markets are seeing higher volume operations by providers such as Google Wing and Zipline for Walmart. While this market incubation can take place with early drones that have unrefined characteristics, scale operations will demand solutions that ensure a high-quality community integration and user experience. One of the most rampant complaints associated with existing deliveries is the relatively high noise levels from even small drones, particularly because these deliveries are happening at their residences in quiet suburban background noise environments. Scale deliveries mean frequent neighborhood incursions with flights occurring at 300-foot altitudes where the drones can be easily heard across many neighboring households and along the trip path. The noise concern is particularly concerning during the final delivery stage where high hover power in close proximities to residences increases the neighborhood noise exposure. Whisper Aero has developed a breakthrough in low noise thrust with demonstrations that have shown the ability for a 55 lb Group 2 drone to be inaudible at altitudes of 200 feet, and noise characteristics that blend into 45 dB background levels found across most suburban neighborhoods at distances of less than 100 feet. Technology characteristics and example noise results will be shared to showcase the ability of delivery drones to provide refined characteristics that can enable these markets to achieve volume deliveries that enable economies of scale, while minimizing neighborhood annoyance.

2 - Parametric Urban Air Mobility Operational Flight Trajectory Modeling and Noise Assessment

Jiacheng Xie, Georgia Institute of Technology, Atlanta, GA, United States, Raphael Gautier, Holger Pfaender, Dimitri Mavris

Urban air mobility (UAM) is an emerging transformational flight concept for future aviation. New flight operations are expected to be carried by advanced aerial vehicles, such as uncrewed aerial systems (UAS) for package delivery and electric vertical takeoff and landing (eVTOL) aircraft for air taxi services. Although UAM promises

significant benefits, it also introduces new challenges, particularly related to environmental noise. Unlike conventional aircraft, UAM vehicles often feature distributed propulsion systems and operate frequently at low altitudes, raising concerns about localized community noise impacts. The objective of this research is to develop a parametric modeling framework to simulate UAM flight operations and assess the associated community noise exposure. The framework consists of four major elements: 1) determining potential origin and destination (O/D) sites, 2) constructing O/D pairs using a flight demand model developed based on geographic and census data, 3) generating operational flight trajectories via a grid-based path planning algorithm constrained by airspace regulations, and 4) simulating noise propagation along the trajectories between operating vehicles and virtual receivers. The proposed methodology is applied to two use cases: UAS package delivery in Atlanta area and eVTOL passenger transport in the San Francisco Bay Area. Results provide insights into the spatial distribution of noise impacts and support data-driven planning for sustainable UAM deployment.

3 - The Future of Urban Mobility in Transportation and Delivery

Surnaik Srivastava, Walmart, Santa Clara, CA, United States

The drone delivery revolution isn't about flying technology—it's about reimagining how goods and services move through urban spaces. While the hardware has matured dramatically, successful deployment hinges on understanding exactly what value customers need and how to deliver it consistently. This session cuts through the hype to examine what makes drone programs succeed or fail. Drawing from real-world pilots across diverse cities and sectors, we'll explore how to identify genuine customer needs that drones can uniquely address, from emergency medical supplies to routine e-commerce fulfillment. We'll walk through the critical decisions that shape drone value propositions: which use cases to prioritize, how urban context influences service design, and what operational trade-offs determine long-term viability. The emphasis is on practical evaluation—how do you assess market readiness, navigate regulatory landscapes, and build services that scale beyond pilot programs? Rather than promoting technology for its own sake, we'll examine how to align drone capabilities with genuine customer problems, regulatory requirements, and business economics. The result is a clear methodology for assessing drone opportunities and building programs that scale. With insights drawn from omnichannel retail, this session is ideal for anyone in transportation, logistics, or strategy roles looking to stay ahead of the curve.

Supply Chain Optimization at Amazon

Invited Session

The Practice Section of Informs

Chair: Garrett van Ryzin, Amazon, New York, NY, United States

1 - Vendor Collaboration Using Consensus Planning

Garrett van Ryzin, Amazon, New York, NY, United States

Consensus Planning Protocol (CPP) is a distributed optimization framework used at Amazon to modularize and scale supply chain optimization problems. In this talk, we present our ongoing work on extending CPP as a platform for collaboration with external vendors. This involves modifying the CPP subsidy payments to make them incentive compatible using mechanism design principles. We describe both concepts and implementation.

2 - Multiple Response Agents: Fast, Feasible, Approximate Primal Recovery for Dual Optimization Methods

Yicheng Bai, Amazon, New York, NY, United States, Tetiana Parshakova, Garrett van Ryzin, Stephen Boyd

We consider the problem of minimizing the sum of agent functions subject to affine coupling constraints. Dual methods are attractive for such problems because they allow the agent-level subproblems to be solved in parallel. However, achieving primal feasibility with dual methods is a challenge; it can take many iterations to find sufficiently precise prices that recover a primal feasible solution, and even with exact prices primal feasibility is not guaranteed without strict convexity. To overcome this limitation, we propose a novel primal recovery method, multiple-response agents (MRA), that is able to rapidly reduce primal infeasibility, tolerating some degree of suboptimality, and can be used with any dual algorithm.

3 - Multi-Objective Optimization in Assortment Planning for Speed Deliveries

Suleyman Karabuk, Amazon, Bellevue, WA, United States, Ozan Candogan, Jonathan Jonker, Nanjing Jian

Assortment planning for Amazon's Sub-Same Day (SSD) program involves balancing multiple competing objectives, including selection breadth, depth, Contribution Profits (CP), Customer Instock Value (CIV), Demand Penetration, and Glance Value In-Stock Speed (GVIS), etc. Traditional approaches maximize weighted sums of these objectives, exploring trade-offs by varying weights across grids to characterize the Pareto frontier. However, this method becomes computationally expensive, especially when dealing with a large number of objectives. To address this challenge, we present a novel performance space characterization technique inspired by cutting-plane methods that iteratively constructs polyhedral inner and outer approximations of achievable performance. This approach efficiently maps the performance space—the set of all attainable objective values under various policies—thereby fully characterizing the Pareto frontier. This approach has been successfully applied to Amazon Search ranking. In this paper, we extend this methodology to Amazon's SSD assortment planning.

Use Cases in Data Driven Decision Making

Invited Session

Practice Track

Chair: Dayana Cope, Delta Air lines, 200 Mimosa Dr, Decatur, GA, 30030, United States

1 - Welcome Aboard Southwest Airlines Flight 737: Optimizing Pilot Training

Whitney Conner, Southwest Airlines, Louisville, KY, United States, Megan Kendrick

Sit back and relax as we embark on an adventure through Pilot training at Southwest Airlines. We're going to have an easy take-off where we learn about a Pilot's journey from New Hire to Captain. At cruising altitude, we'll give you the 30,000 foot view of 5 MILP Optimizers that we use to schedule training events and assign trainees and facilitators. As we reach our final destination, we'll dive into the details of the model that schedules hundreds of training events each month, efficiently using limited training resources and balancing other operational priorities.

2 - How Delta Air Lines Approaches New Technology: Strategies for a Successful Tech Journey

Amin Lalani, Delta Air Lines, Atlanta, GA, United States

Despite the rapid pace of innovation, customers still expect human-centered support. While self-service options provide convenience, many prefer to speak to someone to ensure their concerns are acknowledged. However, technology should not hinder the human experience; instead, it can serve as a tool to improve interactions and outcomes.

One of the digital product leaders of Airport Customer Service Tools and Technology, Amin Lalani, will share his insights on implementing new technology at Delta Air Lines. With a strong emphasis on customer focus, Amin and his team aim to create seamless, human-first experiences while enabling the frontline to deliver operational reliability.

He will introduce frameworks for initiating transformation and leading with human-centered initiatives, covering:

- Strategies for customer education and engagement
- Emerging trends in Employee and Customer Experience technology
- Tips for enhancing collaboration and securing buy-in across teams and organizations

3 - Gain Efficiency Using Generative Ai

Indu Tiwari, Delta, Apple Valley, MN, United States, Purnajyoti Bhaumik, Pavithra Karthikeyan, Mohammed Behbooei

Delta Air Lines is harnessing the transformative power of Generative AI (GenAI) to enhance operational efficiency, empower employees, and elevate customer experiences. By integrating GenAI with traditional AI and machine learning models, Delta is creating hybrid (ML, NLP, and machine vision) solutions that are both scalable and cost-effective. These technologies are being deployed across various areas—from backend operations like crew scheduling and supply chain management to customer-facing services such as chatbots and virtual assistants that handle routine inquiries. This allows human agents to focus on more complex issues, often supported by Retrieval-Augmented Generation (RAG) systems. GenAI can also generate real-time reports, forecasts, and summaries, enabling faster, context-aware decision-making for executives and staff alike.

The company has seen measurable benefits, including a 10% decrease in customer handling time (CHT) and reduced escalations at call centers. Employees across departments are accelerating their productivity with tools like Copilot and Q for Developer. With every customer journey generating vast amounts of data, Delta emphasizes the need for standardized, enterprise-grade GenAI products governed by robust evaluation methods. These go beyond classical AI techniques to ensure quality, safety, and user-friendliness.

Recognizing the importance of responsible innovation, Delta has implemented a comprehensive governance framework that prioritizes ethical, secure, and transparent AI usage. This includes strict guidelines on data handling, human oversight, and risk management to maintain trust and regulatory compliance. Through a combination of internal development and third-party solutions, Delta is strategically leveraging GenAI to drive innovation and create meaningful value for both customers and employees.

OR for Defense Planning

Invited Session

Military and Security

Chair: Isabella Sanders, Arizona State University, Newburgh, NY, United States

1 - Retrieval-Augmented Generation for Adversarial Defense Planning

Tahir Ekin, Texas State University, San Marcos, TX, United States, Laxmi Shaw, Krishna Sai Mandadapu

Capturing the uncertainty in attacker goals and strategies has long been a critical challenge in defense planning. This talk introduces a novel approach that leverages Retrieval-Augmented Generation (RAG) to simulate diverse attack scenarios and help model attacker uncertainty. By generating realistic adversarial actions and goals based on historical data and expert knowledge, our method provides a dynamic and adaptable representation of potential threats. These simulated scenarios are integrated into a probabilistic decision-making framework using Adversarial Risk Analysis, enabling defense planners to assess risks and optimize responses under uncertainty. We further discuss the computational techniques required to scale this approach, making it suitable for complex defense environments with multiple decision-makers. This approach provides a robust foundation for adaptive, data-driven defense planning in adversarial settings.

2 - The Autonomous Aircraft Search and Service Problem

John Goodwill, Air Force Institute of Technology, WPAFB, OH, United States, Matthew Robbins, Brian Lunday, Nicholas Yielding

Autonomous air vehicles (AAVs) subjected to partial observability and intermittent communications must make sequential decisions under uncertainty while performing a team search and service mission. We formulate a Markov based sequential decision process model of this autonomous aircraft search and service (A2S2) problem and solve it using a blended optimization and reinforcement learning based approach. The team of AAVs must collectively locate and service multiple, moving ground-based targets. We develop a centralized training, decentralized execution (CTDE) multi-agent reinforcement learning (MARL) algorithm that periodically conducts re-planning via a mathematical program, informing subsequent AAV decisions. MARL policies generated by our algorithm are compared to those generated by independent deep Q-networks (IDQN). Designed computational experiments investigating several problem instances show differences with respect to quality of solution, computational efficiency, and robustness over varying mission conditions. Preliminary experimentation suggests that our novel algorithm outperforms established MARL policies.

3 - Simulation Based Integrated Airline Recovery

Nirav Lad, The Air Force Institute of Technology, WPAFB, OH, United States, Lance Champagne

Disruptions occur regularly in transportation and impact power project capabilities. A disruption is an interruption in the normal course of scheduled operations. Similarities exist between military and civilian air transportation operations. Moreover, military air transportation operations are reliant on civilian airlines participating in the Civil Air Reserve Fleet (CRAF) for power projection. This research focuses on civilian airline operations due to data availability for simulation and acknowledges the similarities in military and civilian operational procedures. Airline Operation Control Centers (AOCCs) manage and mitigate disruptions by rescheduling flight operations to minimize losses and maximize passenger throughput. This multi-objective problem is known as the airline recovery problem and consists of three sub-problems addressing airplanes, crews, and passengers respectively. The aircraft recovery sub-problem is generally the first of these three sub-problems solved with the assumption that passenger impacts are accounted for and crews are available. Initial study for the airline recovery problem focused on optimization techniques to solve the aircraft recovery sub-problem within limited scenarios. Recently, machine learning approaches have shown promise at solving integrated airline recovery. Simulation-based approaches remain scarce and can accommodate reinforcement learning as well as optimization methods. This research contributes an integrated airline recovery problem simulation-based approach implementation that leverages reinforcement learning to aid decision makers in aircraft and schedule recovery. Additionally, the research explores synergy with the Digital Twin concept for air mobility operations.

4 - Weighted Rank Aggregation for Portfolio Optimization: Visualizing and Making Sense of Multiple Ranked Lists

Tyler Perini, U.S. Naval Academy, Annapolis, DC, United States

The problem of interpreting or aggregating multiple rankings is common to many real-world applications. Perhaps the simplest and most common approach is a weighted rank aggregation, wherein a (convex) weight is applied to each input ranking and then ordered. This work presents a new tool for visualizing and displaying ranking information for the weighted rank aggregation method with three input ranked lists. Traditionally, the aim of rank aggregation is to summarize the information from the input rankings and provide one final ranking that hopefully represents a more accurate or truthful result than any one input ranking. While such an aggregated ranking is, and clearly has been, useful to many applications, it also obscures information. With a weight set visualization, we show the wealth of information that is available for all alternative rank aggregations due to its nice structure. We apply weight set decomposition to the set of convex multipliers, study the properties useful for understanding this decomposition, and visualize the indifference regions. This methodology reveals information—that is otherwise collapsed by the aggregated ranking—into a useful, interpretable, and intuitive decision support tool. Included are multiple illustrative examples, along with heuristic and exact algorithms for computing the weight set decomposition.

5 - Tropical Geometry in Neural Networks: a Novel Defense Against Adversarial Attacks

Kurt Pasque, Navy, Pensacola, FL, United States

Neural networks, though powerful, are highly susceptible to adversarial attacks, which can severely impact their reliability and performance in critical applications, especially within the Department of Defense (DoD). This thesis employs Tropical Convolutional Neural Networks (TCNN), a novel technique leveraging tropical geometry to enhance neural network robustness against adversarial attacks. By reconfiguring neural networks to use a tropical embedding layer as the final layer, this

approach significantly improves resistance to attacked input data without compromising model accuracy, complexity, or training time. The research includes comprehensive experiments on image classification tasks across multiple datasets, demonstrating that TCNNs maintain higher accuracy under adversarial conditions compared to identically structured traditional models. This work not only contributes to the advancement of secure artificial intelligence (AI) applications in defense but also opens new avenues for future research in neural network robustness.

Control of Stochastic Networks

Invited Session

Applied Probability Society

Chair: Nasser Barjesteh, University of Toronto, Toronto, ON, Canada

Co-Chair: Amir Alwan, University of Wisconsin-Milwaukee Lubar College of Business, Pewaukee, 53202, United States

1 - Analysis of Interactions Between Strategic Customers and Strategic Servers

Yueyang Zhong, London Business School, London, United Kingdom

Service system design is often informed by queueing theory. Traditional queueing theory assumes that customers are indefinitely patient and servers work at constant speeds. That is reasonable in computer science and manufacturing contexts. However, customers and servers in service systems are people, and, in contrast to jobs and machines, often make strategic joining and work speed decisions. We develop a game-theoretic many-server Markovian queueing model with a finite buffer in which the buffer is endogenously induced by strategic customers' joining decisions, and the work speeds emerge as the solution to a non-cooperative game among strategic servers. In an asymptotic regime in which demand becomes large, we establish necessary and sufficient conditions for the existence of individual equilibria. Based on our explicit characterization of individual equilibria and the social optimum, we also explore the behavior of customer welfare, server welfare, and social welfare at equilibrium and under the social optimum.

2 - A Whittle Index Approach to Schedule Jobs with Time-Varying Holding Cost

Zhouzi Li, Carnegie Mellon University, Pittsburgh, PA, United States, Keerthana Gurushankar, Mor Harchol-Balter, Alan Scheller-Wolf

Scheduling a stream of jobs whose holding cost changes over time is a classic and practical problem. Specifically, each job is associated with a holding cost (penalty), where a job's instantaneous holding cost is some increasing function of its class and current age (the time it has spent in the system since its arrival). The goal is to schedule the jobs to minimize the time-average total holding cost across all jobs.

The seminal paper on this problem, by Van Mieghem in 1995, introduced the generalized c-mu rule for scheduling jobs. Since then, this problem has attracted significant interest but remains challenging due to the absence of a finite-dimensional state space formulation.

Consequently, subsequent works focus on more tractable versions of this problem.

This paper returns to the original problem, deriving a heuristic that empirically improves upon the generalized c-mu rule and all existing heuristics.

Our approach is to first translate the holding cost minimization problem to a novel Restless Multi-Armed Bandit (R-MAB) problem with a finite number of arms. Based on our R-MAB, we derive a novel Whittle Index policy, which is both elegant and intuitive.

3 - Optimal Batched Scheduling of Stochastic Processing Networks Using Atomic Action Decomposition

Zhanhao Zhang, Cornell University, Ithaca, NY, United States, Jim Dai, Manxi Wu

Stochastic processing networks have broad applications in healthcare, transportation, and communication networks. Despite advancements in MDP algorithms and computational resources, optimizing control policies for these networks remains challenging due to the curse of dimensionality, as the number of feasible server assignments grows exponentially with the number of servers.

We observe that many of these systems have the reward decomposability property, where the total reward from the joint assignment of all servers can be expressed as the sum of individual server rewards. By leveraging this property, we propose the atomic action decomposition framework that reduces the original MDP, whose action size scales exponentially with the number of servers, to a smaller MDP that has a constant action size, without loss of optimality. We demonstrate that this property holds widely across various applications.

Moreover, by integrating our atomic action decomposition into a popular RL algorithm PPO, we empirically show that our approach yields superior control policies in applications such as internet switch scheduling, hospital inpatient admissions, and ride-hailing.

4 - Greedy Matching of Impatient Agents: the Role of Inventory

Angela Kohlenberg, University of Michigan, Ann Arbor, MI, United States

We study dynamic matching with heterogeneous demand and supply that arrive over time and abandon if not matched before their patience expires. A match consists of a compatible demand-supply pair, and yields a demand-dependent reward. At each moment, a controller decides whether to match and, if so, which pair to match. A fundamental trade-off underlies optimal match timing: greedy (immediate) matching ignores the benefit of holding inventory (waiting supply) for better future matches, while delayed matching risks abandonment of supply or demand. We propose the family of Restricted Greedy (RG) policies, which immediately (i.e., greedily) executes matches within an optimized subset of compatible demand-supply pairs and does not perform matches outside this subset. A knapsack-like algorithm identifies the network design: the optimal subset of the compatibility graph. We identify conditions under which RG is scale optimal: its reward loss due to abandonment is on the same order as the optimal policies for all relevant parameters (arrival rates, impatience rates, and match rewards). These conditions reveal why, in the presence of abandonment, static network design combined with greedy matching is often near-optimal. They formalize the intuition that abandonment compromises the controller's ability to fine-tune inventory levels, and therefore, system performance.

5 - Dynamic Control of Multiclass Omnichannel Hybrid Production Systems: Applications to Dynamic Pricing in Restaurants

Amir Alwan, University of Wisconsin-Milwaukee Lubar College of Business, Pewaukee, WI, United States, Nasser Barjesteh

The rise of omnichannel production systems has transformed various industries, introducing new challenges in demand and operations management. One notable development is the adoption of dynamic pricing in omnichannel restaurants. Motivated by these trends, we develop a stochastic processing network model for an omnichannel hybrid production system serving heterogeneous, price- and delay-sensitive customers. The firm offers a mix of make-to-order (MTO) and make-to-stock (MTS) goods, available through both walk-in and online channels, at multiple quote times. The objective is to maximize the long-run average expected profit through dynamic pricing, production scheduling, and order rejection decisions. MTO orders incur both earliness and tardiness costs, while MTS orders face tardiness and inventory holding costs. Walk-in customers have finite patience and may abandon the system if their waiting time is excessive. Since this problem appears analytically intractable, we consider an approximating Brownian control problem in the heavy-traffic regime. We prove that the optimal policy is a two-sided barrier policy with a state-dependent drift rate, for which we derive a closed-form solution. We then propose a joint dynamic pricing, scheduling, and rejection policy by interpreting this solution in the context of the original production system. Finally, we demonstrate the effectiveness of our proposed policy through a comprehensive simulation study and offer several managerial insights tailored to our canonical example of an omnichannel restaurant.

Operations Research and Analytics at Norfolk Southern

Invited Session

Railway Applications

Chair: Yudi Pranoto, Norfolk Southern Corporation, Atlanta, GA, United States

1 - Synchronize Train Schedules for Freight Rail**Peiheng Li, Norfolk Southern Corporation, Decatur, GA, United States**

Train scheduling contributes the last fundamental decision in an operating plan for freight rail in North America following closely behind blocking and train routing. This problem has combinatorial complexity in nature as it concerns designing train schedules in terms of frequency, operating days, and timing. A scheduling plan involves synchronized train movements and shipment flows. Its evaluation often resorts to simulation. These two features make this real-life problem extremely challenging to solve. This presentation has two goals: (1) review this problem especially its relationship with these train scheduling and timetabling problems reported in literature; (2) summarize an approximation model we develop at Norfolk Southern (NS) as an endeavor on solving this problem. This approximation model is reasonable in accuracy and easy to solve. The numerical tests against the real-life operating plans have proven its effectiveness and efficiency in facilitating the transit of shipments. This approximation model has been successfully integrated with the existing scheduling decision support system at NS and has been rolled out to help design efficient schedule plans and drive productivity.

2 - Or Application at Ns Operations Center**Zahed Shahmoradi, Norfolk Southern, Atlanta, GA, United States**

Norfolk Southern aims to lead safety and efficiency in the operations. The Operation Research team is tasked to advance this goal by applying OR concepts, AI, and simulation to provide insights on optimal tonnage ratings, power assignments, and infrastructure changes for potential speed limit increases. The objective is to drive quick wins by identifying bottlenecks and developing real-time and production ready tools. In one study, we analyzed train consist, speed, and topology data patterns to quantify train stall risk. The proposed methodology is used to enhance the existing tonnage rating methodology into a dynamic approach that can both prevent train stalls and unlock tonnage capacity by utilizing track topology features. Accurate speed limit is critical in optimizing network velocity and fuel efficiency. In another study, a track topology scanning algorithm is designed to search, simulate, and propose new speed limits with potential fuel and time savings and minimum capital investment. The process first filters out segments conform to certain geometry patterns (e.g., valley), where train speed can benefit from gravity. The candidate solutions are then analyzed in an automated simulation and statistical analysis pipeline to generate a final short list optimized to meet engineering team's criteria.

3 - Or Applications in Intermodal Operations**Gita Ayu, Norfolk Southern, Atlanta, GA, United States**

Intermodal transportation is a strategic approach that maximizes the strengths of each transport mode by loading cargo into containers, enabling seamless movement between modes. The life cycle of a shipment begins at ingate at the origin and concludes at outgate at the destination, utilizing terminal resources to store and transfer shipments within and between intermodal terminals. As one of the leading players in the intermodal industry, Norfolk Southern leverages its extensive network of terminals, access to major East Coast container ports, and partnerships with North American intermodal rail providers to ensure efficient and reliable goods movement. At Norfolk Southern, we develop, maintain, and continuously enhance our in-house, data-driven tools to support operations. These tools include shipment forecasting, railcar tracking, and terminal resource optimization. We will present an overview of each tool with their use cases.

4 - Operating Plan Optimization**Gunnar Feldmann, Norfolk Southern, Atlanta, GA, United States**

The operating plan drives all car movements at Norfolk Southern. It is revised on a daily basis by the Network Design Optimization group (NDO) to ensure the most efficient routing of cars throughout the network. NDO has several optimization tools at their disposal to achieve this goal. At the traffic side, Market, Research, and Forecast (MR&F) provides a judgemental as well as a model based volume forecast. This forecasted volume feeds into the offline plan developer tool to simulate the traffic movement based on the blocking and train plan. To achieve the most efficient routing and to sustain a continuous refinement of the operation plan, NDO utilizes additional decision support tools. For the blocking plan a very large scale neighborhood search heuristic model has been deployed, and for the train plan a heuristic routing model has also been ran. In this presentation, we will focus on the afore-mentioned models and, more specifically, how they contribute to an optimized operating plan.

Decision-making in Structured Stochastic Systems

Invited Session

Applied Probability Society

Chair: Weina Wang, Carnegie Mellon University, Pittsburgh, PA, United States

1 - New Approaches for Restless Bandits and Weakly Coupled Mdp**Yige Hong, Carnegie Mellon University, Pittsburgh, PA, United States, Weina Wang, Qiaomin Xie, Yudong Chen, Xiangcheng Zhang**

In this talk, we present recent progresses on the classic restless bandit (RB) problem and its generalization, weakly-coupled Markov decision processes (WCMDP), under the long-run average-reward objective. These problems model the resource allocation and control of a potentially large number of weakly-coupled “arms”, each with a state that evolves dynamically. The RB and WCMDP problems have a long history and wide range of applications, but they are challenging to solve due to the high-dimensional joint state space.

In our recent line of work, we introduce novel policies and analysis tools that pushes the existing asymptotic optimality results beyond the classic setting. This includes removing a long-standing global attractor assumption, and allowing fully heterogeneous arms. We also establish exponentially small optimality gaps for non-degenerate RBs, under weaker-than-standard conditions. Our approach highlights a novel way of exploiting the weakly-coupled structure, by matching the long-term behavior of some subsystems with simpler processes. This is in contrast with the classic index policies, which are mainly greedy policies with less control of the system’s long-term behavior.

2 - Exploiting Exogenous Structure for Sample-Efficient Reinforcement Learning

Jia Wan, Massachusetts Institute of Technology, Cambridge, MA, United States, Sean Sinclair, Devavrat Shah, Martin Wainwright

We study Exo-MDPs, a structured class of Markov Decision Processes (MDPs) where the state space is partitioned into exogenous and endogenous components. Exogenous states evolve stochastically, independent of the agent’s actions, while endogenous states evolve deterministically based on both state components and actions. Exo-MDPs are useful for applications including inventory control, portfolio management, and ride-sharing. Our first result is structural, establishing a representational equivalence between the classes of discrete MDPs, Exo-MDPs, and discrete linear mixture MDPs. Specifically, any discrete MDP can be represented as an Exo-MDP, and the transition and reward dynamics can be written as linear functions of the exogenous state distribution, showing that Exo-MDPs are instances of linear mixture MDPs. For unobserved exogenous states, we prove a regret upper bound of $\tilde{O}(H^{\frac{3}{2}}\sqrt{K})$ over KS trajectories of horizon H , with d as the size of the exogenous state space, and establish nearly-matching lower bounds. Our findings demonstrate how Exo-MDPs decouple sample complexity from action and endogenous state sizes, and we validate our theoretical insights with experiments on inventory control.

3 - Sample-Path Comparison of Fcfm and ROS in One- and Two-Sided Matching Queues

Runhan Xie, University of California, Berkeley, Berkeley, CA, United States, Elene Anton, Kristen Gardner, Rhonda Righter

We consider a matching model with bipartite compatibilities and Poisson arrivals of items to both sides. The arriving items may queue on one or both sides. We find conditions under which FCFM has better performance than random matching in terms of minimizing the number of waiting items in the transient regime. We also show that under the same conditions, the LQ (match the longest compatible queue) is optimal in a strong sense among policies that can use all of the state information.

4 - Optimal Single-Policy Sample Complexity and Transient Coverage for Average-Reward Offline RL

Matthew Zurek, University of Wisconsin-Madison, Madison, WI, United States, Guy Zamir, Yudong Chen

We study offline reinforcement learning in average-reward MDPs, which presents increased challenges from the perspectives of distribution shift and non-uniform coverage, and has been relatively underexamined from a theoretical perspective. While previous work obtains performance guarantees under single-policy data coverage assumptions, such guarantees utilize additional complexity measures which are uniform over all policies, such as the uniform mixing time. We develop sharp guarantees depending only on the target policy, specifically the bias span and a novel policy hitting radius, yielding the first fully single-policy sample complexity bound for average-reward offline RL. We are also the first to handle general weakly communicating MDPs, contrasting restrictive structural assumptions made in prior work. To achieve this, we introduce an algorithm based on pessimistic discounted value iteration enhanced by a novel quantile clipping technique, which enables the use of a sharper empirical-span-based penalty function. Our algorithm also does not require any prior parameter knowledge for its implementation. Remarkably, we show via hard examples that learning under our conditions requires coverage assumptions beyond the stationary distribution of the target policy, distinguishing single-policy complexity measures from previously examined cases. We also develop lower bounds nearly matching our main result.

1 - Incentivizing Healthy Food Choices Using Add-on Bundling: a Field Experiment

Nymisha Bandi, McGill University, Montreal, QC, Canada, Maxime Cohen, Saibal Ray

How can retailers incentivize customers to make healthier food choices? Price, convenience, and taste are known to be among the main drivers behind such choices. Unfortunately, healthier food options are often expensive and infrequently promoted. Recent efforts in deploying healthy nudges to incentivize customers toward healthier food choices have been observed. In this paper, we conducted a field experiment with a global convenience store chain to better understand how different add-on bundle promotions influence healthy food choices. We considered three types of add-on bundles: (i) an unhealthy bundle (when customers purchased a coffee, they could add a pastry for \$1), (ii) a healthy bundle (offering a healthy snack as an add-on), and (iii) choice bundle (offering either a pastry or a healthy snack). In addition to our field experiment, we conducted an online lab study to strengthen the validity of our results. We found that offering healthy snacks as part of an add-on bundle significantly increased healthy purchases (and decreased unhealthy purchases). Surprisingly, this finding continued to hold for the choice bundle, that is, even when unhealthy snacks were concurrently on promotion. Unfortunately, we did not observe a long-term stickiness effect, meaning that customers returned to their original (unhealthy) purchase patterns once the healthy or choice bundle was discontinued. Finally, we show that offering an add-on choice bundle is also beneficial for retailers, who can earn higher revenue and profit.

2 - Differential Game Theoretic Models for Designing Water Conservation Incentives

Behnam Momeni, George Mason University, Fairfax, VA, United States, Shima Mohebbi

The growing concern over water scarcity and the management of freshwater is common worldwide. Voluntary incentives, such as payments to water users, offer a potential strategy to reduce conflicts and water consumption. This study formulates non-cooperative differential game-theoretic framework to design incentive schemes for water users, both groundwater and surface water, located in a river basin network. A non-governmental organization (NGO) acts as a key player, providing conservation incentives that account for both vertical and horizontal interactions among water users. The model designs incentives based on the characteristics of each water user and addresses scalability challenges as the network size grows. We propose solution methods for both convex and nonconvex settings, including Karush-Kuhn-Tucker conditions, Value Iteration, and Basis Function Approximation. Parametric analyses assess how model parameters influence solution methods and decision-making outcomes.

3 - Optimal Resource Allocation to Minimize Errors when Detecting Human Trafficking

Abhishek Ray, George Mason University, Fairfax, VA, United States, Viplove Arora, Kayse Maass, Mario Ventresca

Accurately detecting human trafficking is particularly challenging due to its covert nature, difficulty in distinguishing trafficking from non-trafficking exploitative conditions, and varying operational definitions. Typically, detecting human trafficking requires resource-intensive efforts from resource-constrained anti-trafficking stakeholders. Such measures may need personnel training or machine learning-based identification technologies that suffer from detection errors. Repeated usage of such measures risks biasing detection efforts and reducing detection effectiveness. Such problems raise the question: “How should imperfect detection resources be allocated to most effectively identify human trafficking?” As an answer, we construct a class of resource allocation models that considers various optimal allocation scenarios. These scenarios range from optimal location selection for monitoring to optimal allocation of a finite set of imperfect resources, given error rates. We illustrate the applicability

of these models across both human and technology-facilitated detection contexts at the India–Nepal border and in the global seafood industry. Insights from our models help inform operational strategies for allocating limited anti-human trafficking resources in a way that effectively preserves human rights and dignity.

Chair: Zaiwei Chen, Purdue University, West Lafayette, IN, United States

1 - Non-Asymptotic Guarantees for Average-Reward Q-Learning with Adaptive Stepsizes

Zaiwei Chen, Purdue University, West Lafayette, IN, United States

This work presents the first finite-time analysis of average-reward Q -learning with an asynchronous implementation. A key feature of the algorithm we study is the use of adaptive stepsizes that act as local clocks for each state-action pair. We show that the mean-square error of this Q -learning algorithm, measured in the span seminorm, converges at a rate of $\mathcal{O}(\frac{1}{k})$. To establish this result, we demonstrate that adaptive stepsizes are necessary: without them, the algorithm fails to converge to the correct target. Moreover, adaptive stepsizes can be viewed as a form of implicit importance sampling that counteracts the effect of asynchronous updates. Technically, the use of adaptive stepsizes causes each Q -learning update to depend on the full sample history, introducing strong correlations and making the algorithm a non-Markovian stochastic approximation (SA) scheme. Our approach to overcoming this challenge involves (1) a time-inhomogeneous Markovian reformulation of non-Markovian SA, and (2) a combination of almost-sure time-varying bounds, conditioning arguments, and Markov chain concentration inequalities to break the strong correlations between the adaptive stepsizes and the iterates.

2 - Concentration of Variance-Reduced Stochastic Approximation Algorithms

Bulut Boru, University of Minnesota, Minneapolis, IN, United States, Sajad Khodadadian, Martin Zubeldia

In this talk, we consider several variance-reduction techniques for stochastic approximation algorithms, and we go beyond variance by exploring their impact on the distribution of the error. In particular, we show that adding a projection step onto a ball with a slowly increasing radius can lighten the tail of the error from heavy-tailed (up to Pareto) to Gaussian.

3 - What Mathematical Structures Make RL Possible? An Elliptic Theory for Controlled Diffusions

Wenlong Mou, University of Toronto, Toronto, ON, Canada

Reinforcement learning (RL) offers a powerful framework of decision-making in dynamical environments, and recent years have seen a surge of RL applied to continuous-time Markov diffusions. Yet, existing contraction-based RL theory suffers from limitations such as diverging effective horizons, and fails to provide the relevant guidance.

In this talk, I will present recent advances in designing RL algorithms for controlled diffusion processes. I begin by exploring how *uniform ellipticity*—a foundational property of Markov diffusions—enables RL with rigorous theoretical guarantees. Among other findings, I will demonstrate how elliptic structures makes RL as easy as supervised learning, a striking contrast to the inherent difficulties of RL in unstructured Markov decision processes.

4 - $O(1/K)$ Finite-TIME Bound for Non-Linear Two-Time-Scale Stochastic Approximation

Siddharth Chandak, Stanford University, Stanford, CA, United States

Two-time-scale stochastic approximation is an algorithm with coupled iterations which has found broad applications in reinforcement learning, optimization and game control. While several prior works have obtained a mean square error bound of $O(1/k)$ for linear two-time-scale iterations, the best known bound in the non-linear contractive setting has been $O(1/k^{2/3})$. In this work, we obtain an improved bound of $O(1/k)$ for non-linear two-time-scale stochastic approximation. Our result applies to algorithms such as gradient descent-ascent and two-time-scale Lagrangian optimization. The key step in our analysis involves rewriting the original iteration in terms of an averaged noise sequence which decays sufficiently fast. Additionally, we use an induction-based approach to show that the iterates are bounded in expectation.

Truck Platooning and Vehicle Routing Problems

Invited Session

TSL: Freight Transportation

Chair: Rui Zhang, University of Colorado Boulder, Boulder, CO, United States

1 - Container Drayage Operations with Autonomous Trucks and Platooning

Ziyu Qiu, University of Illinois Chicago, Chicago, IL, United States, Bo Zou, Chi Xie, Mingzhou Jin

Drayage plays a critical role in the national supply chain. While accounting for a small portion of the total distance traveled, drayage contributes a disproportionately large share of the total logistics cost. The connected and autonomous vehicle technologies presents opportunities to enhance the cost efficiency of drayage, but has not been well studied. This research evaluates the impact of autonomous trucks equipped with platooning capabilities on container drayage between intermodal terminal facilities. We develop a series of mixed integer programming models to characterize truck and container movements in time-expanded networks, under multiple scenarios including single (truck type) fleet without platooning, single fleet with platooning, mixed fleet with homogeneous platooning (trucks in a platoon are of the same type), and mixed fleet with heterogeneous platooning. For the last scenario, a linear programming-based approach is further embedded for optimizing truck composition while forming platoons. Extensive numerical experiments are conducted in the context of container drayage in the Chicago metropolitan area. Among the many results, we find that forming smaller platoons are preferred over larger platoons when the energy saving percentages are comparable. In addition, heterogeneous platooning generates greater more benefits than homogeneous platooning. The findings help inform future drayage system operation strategies with autonomous trucks.

2 - Electric-Truck Routing and Platooning with Capacitated Charging Stations

Danesh Hosseinpahani, University of Illinois-Chicago, Chicago, IL, United States, Jialu Yang, Bo Zou, Jane Lin

The integration of truck platooning and electric trucks presents a promising avenue for improving operational efficiency and environmental sustainability in freight transportation. Realizing the energy and cost saving as well as emission reduction benefits requires a holistic design of truck routing, scheduling, and platooning strategies that accounts for practical operational constraints. This study investigates the integrated problem of electric-truck routing and charging scheduling, incorporating key factors such as energy savings from platooning, battery limitations of electric trucks, charging station availability and capacity, mandatory driver rest periods, and the positional configuration of trucks within a platoon (i.e., leaders and followers). The objective is to minimize the total charging cost, travel time cost, and waiting time costs of the system, thereby ensuring timely arrivals across multiple origin–destination (OD) pairs, while simultaneously maximizing the formation of energy-efficient platoons along the routes. A mixed-integer linear program (MILP) is formulated to optimize truck routing, charging, and platooning decisions, while satisfying operational constraints. To solve the problem, we first use Gurobi to solve instances on a small hypothetical network. Then, we propose a Lagrangian Relaxation-based decomposition approach to seek near-optimal solutions for large-scale problems on the Illinois highway network. Extensive numerical experiments are conducted to examine the effectiveness and efficiency of the model and solution approach. The findings offer valuable managerial insights into optimizing electric-truck operations with platooning

3 - Planning of Truck Platooning for Road-Network Capacitated Vehicle Routing Problem

Zhibin Chen, New York University Shanghai, Shanghai, China, People's Republic of, Yilang Hao, Xiaotong Sun, Lu Tong

In real-world logistics, each truck may need to serve multiple customers located at different places, and the operator managing a fleet of trucks thus has to determine not only the routing and time schedules of each truck but also the set of customers allocated to each truck and their sequence to visit. This is well known as a capacitated vehicle routing problem with time windows (CVRPTW), and considering the application of truck platooning in such a problem entails new modeling frameworks and tailored solution algorithms. In light of this, this study makes the first attempt to optimize the truck platooning plan for a road-network CVRPTW in a way to minimize the total operation cost, including vehicles' fixed dispatch cost and energy cost, while fulfilling all delivery demands within their time window constraints. Specifically, the operation plan will dictate the number of trucks to be dispatched, the set of customers, and the routing and time schedules for each truck. In addition, the modeling framework is constructed based on a road network instead of a traditional customer node graph to better resemble and facilitate the platooning operation. A 3-stage algorithm embedded with a "route-then-schedule" scheme, Dynamic Programming, and Modified Insertion heuristic, is developed to solve the proposed model in a timely manner. Numerical experiments are conducted to validate the proposed modeling framework, demonstrate the performance of the proposed solution algorithm, and quantify the benefit brought by the truck platooning technology.

4 - A Two-Dimensional Vehicle Loading Problem with Heterogeneous Fleet and Delay Minimization

Juan morande, Auburn University, auburn, AL, United States, Juan Carlos Pina-Pardo, Mario Velez, Daniel Silva, Alice Smith

The approach presented in this paper not only increases the efficiency of existing delivery networks but also quantifies the effects of considering two dimensions when evaluating fleets and delivery routes. By solving the proposed problem in a timely manner, decision makers can plan deliveries along fixed routes on a daily basis. By showing the value of a two-dimensional approach in this case, the paper also contributes to the literature by showing the value of exploiting all the dimensions available in packing problems. Also, the paper gives a benchmark on the proposed problem for future work and methods. Finally, the paper also brings to attention the need for a rehandle minimization strategy when designing delivery networks. While in one-dimensional problems the optimal order in which trucks should be loaded is trivial and easily decided by any operator, when using two dimensions this problem requires a systematic approach to be solved.

5 - Effectation: An Exact Solution Approach for the Formation and Routing of Worker Teams

Rui Zhang, University of Colorado Boulder, Boulder, CO, United States, Jiliu Li, Jinfeng Yang, Nan Huang

Real-world applications often require tracking resource usage over time. One such application is the Worker Team Formation and Routing Problem (WTFRP), proposed by Dall'Olio and Kolisch (2023), which aims to improve airport ground-handling operations. The WTFRP involves scheduling multiple trips with time windows, forming teams with hierarchical and downgrade-compatible skills, and accounting for team-dependent task durations. A major challenge lies in tracking worker availability by skill level across the entire planning horizon, which is difficult for traditional mathematical programming approaches. Rather than discretizing time, this paper proposes an exact solution method in continuous time. We model WTFRP as an infinite integer program with infinitely many variables and constraints. To address its LP relaxation, we propose Effective Time-Point Detection (EFFECTION), a method that dynamically identifies time points to generate both variables and constraints. Building on EFFECTION, we develop Enumeration-Check-and-Switch (ECS). ECS includes: Enumeration, which fixes promising variables; Check, which verifies solution feasibility; and Switch, which alternates between the original and relaxed models. EFFECTION is embedded within ECS to guide the detection of effective time points. In the computational experiments on a set of known instances, we show that ECS not only produces better solutions but also achieves them significantly faster, up to two orders of magnitude, compared to the existing method. Furthermore, we highlight the capability of EFFECTION in solving problems in continuous-time settings on a new set of instances. The results underscore the importance of considering finer time resolutions, which leads to higher-quality solutions for airport ground-handling operations.

Importance Sampling: Methods and Applications

Invited Session

Simulation

Chair: Dohyun Ahn, CUHK, Shatin, Hong Kong

1 - New Bounds and Truncation Boundaries for Importance Sampling

Yijuan Liang, Southwest University, Chongqing, China, People's Republic of, Guangxin Jiang, Michael Fu

Importance sampling (IS) is a technique that enables statistical estimation of output performance at multiple input distributions from a single nominal input distribution, commonly used in Monte Carlo simulation for variance reduction and in machine learning applications for reusing historical data, but its effectiveness can be challenging to quantify. We establish a new result showing the tightness of polynomial concentration bounds for classical IS likelihood ratio (LR) estimators. To address potentially high variance, we propose new truncation boundaries when using a truncated LR estimator, establishing upper concentration bounds that imply an exponential convergence rate. Numerical experiments illustrate the contrasting convergence rates of the various LR estimators and the effectiveness of the newly proposed truncation-boundary LR estimators for examples from finance and machine learning.

2 - Reusing Historical Trajectories in Natural Policy Gradient via Importance Sampling

Yuhao Wang, Georgia Institute of Technology, Atlanta, GA, United States, Yifan Lin, Enlu Zhou

Reinforcement learning provides a mathematical framework for learning-based control, whose success largely depends on the amount of data it can utilize. The efficient utilization of historical trajectories obtained from previous policies is essential for expediting policy optimization. Empirical evidence has shown that policy gradient methods based on importance sampling work well. However, existing literature often neglect the interdependence between trajectories from different iterations, and the good empirical performance lacks a rigorous theoretical justification. In this paper, we study a variant of the natural policy gradient method with reusing historical trajectories via importance sampling. We show that the bias of the proposed estimator of the gradient is asymptotically negligible, the resultant algorithm is convergent, and reusing past trajectories helps improve the convergence rate.

3 - Wasserstein Distributionally Robust Rare-Event Simulation

Dohyun Ahn, The Chinese University of Hong Kong, Shatin, Hong Kong, Lewen Zheng

Classical rare-event simulation methods mostly rely on precise knowledge of the underlying probability distributions, which limits their effectiveness under distributional uncertainty. To address this limitation, we develop a novel simulation framework for estimating rare-event probabilities under such distributional uncertainty. Specifically, our approach computes a distributionally robust rare-event probability bound over a family of distributions defined by a Wasserstein ball around a nominal Gaussian model. By exploiting a dual characterization of this bound and the concept of conditional importance sampling, our framework introduces a two-stage estimation procedure that is simple to implement. We prove the strong efficiency of the proposed method and demonstrate its superior numerical performance compared to existing approaches.

4 - Importance Sampling for Latent Dirichlet Allocation

Ayeong Lee, Columbia University, New York, NY, United States, Paul Glasserman

Latent Dirichlet Allocation (LDA) is a popular method in Natural Language Processing (NLP) for finding topics in text data. Evaluating an LDA model entails estimating the expected likelihood of held-out documents. This is commonly done through Monte Carlo simulation, which is prone to high relative variance. We propose an importance sampling estimator for this problem and characterize the theoretical asymptotic statistical efficiency it achieves in large documents. We illustrate the method in simulated data and in a dataset of news articles.

5 - Start Safe: Configuring Optimization Algorithms for Decision-Making Under Extreme Risks

Wasin Meesena, Columbia University, New York, NY, United States, Henry Lam

We consider stochastic optimization where the goal is not only to optimize an average-case objective, but also mitigate the occurrence and impact of extreme catastrophic events. This problem is motivated from safety-aware decision-making and AI training. In particular, in the presence of a simulation model, variance reduction techniques are naturally employed to control estimation errors due to event rarity. We argue, however, that natural attempts to integrate variance reduction into optimization, even executed in a reasonable adaptive fashion, encounters fundamental challenges in terms of guaranteeing realistic runtime when using common stochastic gradient descent algorithms. On a high level, the challenge arises from the extreme sensitivity of tail-based objectives with respect to the decision variables, which renders the failure of traditional Lipschitz-based analyses. We offer remedies based on a notion of "safe initialization", combined with careful update iterations, that allow for finite-time error control. We discuss implications of our findings on safe decision search and extremal predictive modeling.

1 - The Inverse Optimal Value Problem for Linear Fractional Programming

Sina Nadi, University of Pittsburgh, Pittsburgh, PA, United States, Taewoo Lee, Oleg Prokopyev

We study the inverse optimal value problem for linear fractional programming, where the goal is to find the coefficients of the fractional objective function such that the resulting optimal objective function value is as close as possible to some given target value. We show that this problem is NP-hard. Then, we provide some structural results, which are exploited to derive several reformulations and two solution algorithms. The proposed approaches are based on the Charnes-Cooper and parametric transformations.

2 - Optimizing over Graph Neural Networks with An Application to Optimal Brain Tumor Resection

Kaan Çakıroğlu, Bilkent University, Ankara, Turkey, Taghi Khaniyev, Ozlem Karsu, Sahin Hanalioglu

Low-grade gliomas (LGGs) present a critical challenge in neurosurgical oncology due to their slow progression and the brain's adaptive neuroplastic reorganization. While complete resection reduces recurrence risk, it may disrupt reorganized functional networks. Emerging evidence shows partial resection can preserve neurological outcomes without compromising tumor control. However, surgeons lack quantitative tools to preoperatively evaluate these trade-offs. The absence of a computational framework to model resection trade-offs leaves surgical planning reliant on subjective intraoperative assessments rather than predictive network analysis. Our research addresses this gap by formulating the brain tumor resection problem as a mathematical optimization model using graph neural networks (GNNs) where the brain is represented as a multiplex network comprising regions of interest (ROIs) with structural and spatial connectivity. In our formulation, GNNs approximate brain functionality metrics such as global efficiency and modularity, serving as surrogate objective functions within a mixed-integer programming framework. We extend this methodology to bi-objective optimization, systematically analyzing trade-offs between several brain functionality metrics. Our framework provides surgeons with data-driven strategies that balance maximal tumor control with minimal network disruption. It achieves 99% accuracy in predicting postoperative functionality and efficiently approximates the Pareto Frontier of alternatives, enabling precision neurosurgery tailored to individual brain networks.

3 - An Optimization Approach to White Matter Brain Tumor Resection

Taghi Khaniyev, Bilkent University, Ankara, Turkey, Sena Asli Bozkurt, Sahin Hanalioglu, Oya Ekin Karasan

Preserving brain functionality while performing maximal tumor resection remains a central challenge in clinical practice, as current approaches lack a systematic framework to balance tumor removal with functional outcomes. To address this, we propose a mathematical optimization model that preserves network efficiency by resecting a predefined tumor volume. Network efficiency is quantified using the Global Efficiency (GE) metric. To reflect surgical feasibility, the model incorporates spatial contiguity constraints, ensuring that the resected region forms a connected area. To improve scalability, we developed enhanced formulations and an aggregation heuristic that groups physically close nodes, substantially reducing solution times while maintaining solution quality. Our experiments used real brain network data representing healthy white and gray matter regions, with synthetic tumor instances to simulate disruption. First, using a real tumor instance, we compared the "best" resection guided by our model with the "worst" resection, and demonstrated that our approach leads to significantly better preservation of brain network efficiency. We then validated the aggregation heuristic, showing that it drastically reduces computational time while achieving GE values comparable to the original model. Finally we analyzed the impact of tumor characteristics. Larger tumors were found to disrupt the network more severely even before resection, and to yield lower GE values after resection at equal threshold levels. Centrally located tumors also caused greater reductions in GE compared to peripheral tumors of the same size.

4 - A Hybrid Quantum-Classical Approach for Semidefinite Programming Problems

Gizem Ozbaygin, Bilkent University, Ankara, Turkey, Burak Kocuk, Diego Moran

Semidefinite programming plays a key role in optimization, with broad impact across fields like control theory, machine learning, and combinatorial optimization, thanks to its ability to capture complex problems in a tractable, convex framework. Although semidefinite programming problems are polynomially solvable, classical (non-quantum) algorithms can run into difficulties when dealing with large and dense matrices. Majority of the existing algorithms rely on iteratively evaluating positive semidefiniteness of a series of matrices. This is typically the bottleneck of the solution procedure because the algorithmic routines used for checking positive semidefiniteness mostly have cubic scaling with respect to the number of rows (or columns) in the matrices under consideration. In this study, we propose a hybrid quantum-classical framework to solve semidefinite programming problems by deploying quantum computing for the task of evaluating positive semidefiniteness while performing the rest of the computation classically. We present our preliminary findings based on an initial computational study.

5 - A Metamodel-Based General-Purpose Calibration Tool for Simulation Models

Elif Sena Isik, Georgia Institute of Technology, Atlanta, GA, United States, Taghi Khaniyev, Turgay Ayer, Jagpreet Chhatwal, Ismail Fatih Yildirim

Background: Simulation calibration is the process of configuring a simulation model's parameters to improve the agreement between the model output and the observed historical data. For most realistic simulation models, this calibration process can be quite computationally expensive, as it requires running the simulation model for each parameter combination. The inefficient use of computational resources is also a commonly encountered problem in medical decision making. To alleviate this problem, metamodels offer a trade-off between accuracy and computational efficiency for extensive simulative analysis with highly complex parameter space. **Method:** In this study, we propose an efficient metamodel-based calibration tool that any simulation-based study with computational challenges can benefit from. Four approaches (simulation-based calibration, metamodel-based calibration, and two hybrid methods that utilize the simulation and metamodel jointly) were tested to obtain the most effective tool in terms of accuracy and computational cost. **Results:** Metamodel-based calibration result was found to be an accurate indicator of the regions that are likely to provide optimal parameter configuration with a highly significant (approximately 98%) decrease in computational cost. Furthermore, the hybrid approach that utilizes metamodel to limit the search space and simulation to find the optimal configuration was found to have approximately 40% more precise results compared to the simulation-based calibration approach. **Conclusions:** The study displays the potential benefits of metamodeling in the simulation calibration process and offers a metamodel-based tool for calibration that can aid any simulation study with high computational cost.

1 - Hyperplane Trees as Piecewise Linear Surrogates in Engineering Optimization

Carolina Colombo Tedesco, Carnegie Mellon University, Pittsburgh, PA, United States, Ethan Sunshine, John Kitchin, Carl Laird

Advances in Mixed-Integer Programming (MIP) have led to a growing interest in surrogate modelling. In this paradigm, nonlinear relationships between variables are "learned" by fitting a highly flexible function to some data samples. This fitted function must be one that can be formulated in an optimization problem, such as piecewise linear. To date, numerous piecewise linear surrogate modeling architectures have been explored, including ReLU neural networks, decision trees, and linear model decision trees (LMDT)s.

In this presentation, we introduce Hyperplane Trees (HT) as a new regression architecture designed to be embedded in optimization problems. An HT is a decision tree with linear responses in the leaves and linear combinations of variables used for splitting. HTs are more expressive than LMDTs, allowing better accuracy while introducing fewer binary variables. As an extension of decision trees, HTs are very fast and convenient to train on large or small datasets compared to ReLU neural networks.

We will present our implementation of HTs and show examples of their use in engineering optimization problems.

2 - Rigorous Model Uncertainty in Machine Learning Surrogates for Optimization

Carl Laird, Carnegie Mellon University, Pittsburgh, PA, United States, Daniel Varela

Machine learning (ML) surrogates are often embedded in optimization models to replace costly simulations, enable inverse design, and integrate black-box computations into solver-compatible formulations. While effective, these surrogates inevitably introduce approximation errors that can lead to infeasible or unreliable solutions. Recent advances in statistical learning allow to mitigate this issue by quantifying model uncertainty, but most existing methods do not provide rigorous guarantees when ML-derived constraints are integrated into optimization problems.

We propose Conformal Mixed-Integer Constraint Learning (C-MICL), a framework that delivers probabilistic feasibility guarantees for optimization problems with data-driven constraints. Unlike standard mixed-integer constraint learning methods, which may produce systematically infeasible solutions due to model error or limited data, C-MICL leverages conformal prediction to ensure ground-truth feasibility with probability at least $1-\alpha$, under a mild conditional independence assumption. The method accommodates both regression and classification tasks, requires no direct access to the true constraint function, and avoids the scalability bottlenecks of ensemble-based heuristics. Empirical results across real-world applications confirm that C-MICL consistently achieves target feasibility levels, retains strong objective performance, and reduces computational cost relative to existing approaches.

This work helps bringing mathematical optimization and modern ML uncertainty quantification by introducing a principled approach to enforce feasibility guarantees in surrogate-based optimization. Beyond improving robustness, C-MICL highlights how conformal prediction can be systematically integrated into optimization frameworks, enabling more reliable, data-driven decision-making in engineering and operations research.

3 - Integer Programming Formulations of Constrained Inference for Probabilistic Graphical Models

William Hart, Sandia National Laboratories, Albuquerque, NM, United States, Connor Mattes, Frank Qiu

Although probabilistic graphical models (PGMs) have been successfully applied to a wide range of problems, the analysis of many applications naturally needs to account for constraints that are cannot be directly represented with a PGM. For example, in cybersecurity applications the knowledge state of an attacker influences its ability to execute steps in an attack and associated log events. We describe the use of integer programming (IP) formulations to support constrained inference for probabilistic graphical models. IP formulations that have been proposed to compute the maximum a posteriori states of random variables in PGMs. We show how these formulations can be extended to support constrained inference, using simple exemplars to illustrate the potential application of this idea.

Open Energy Modeling

Invited Session

ENRE: Electricity

Chair: Harry van der Weijde, Open Energy Transition, Bayreuth, 2274GA, Germany

1 - Open Modeling in High-Stakes Planning Processes

Harry van der Weijde, Open Energy Transition, Bayreuth, Germany

The transition to a low-carbon energy system demands robust planning tools capable of addressing increasing variability, uncertainty, and the growing importance of system flexibility. In both regulatory and corporate environments, energy modeling is increasingly expected to be not only technically rigorous but also open, transparent, and reproducible. Yet applying open modeling principles in mission-critical contexts poses unique challenges.

This talk presents practical insights from developing open energy models designed for high-stakes applications, including regulatory decision-making in Europe and strategic planning processes at system operators. We focus on two core tensions encountered in this work. First, the challenge of reconciling openness with the need to manage highly sensitive data. This requires the implementation of strict data security protocols, such as isolated computing environments, tiered access controls, and anonymization procedures, without compromising the model's transparency or its accessibility to diverse stakeholders. Second, we address the technical and organizational demands of scalability. Mission-critical modeling often involves running thousands of complex scenarios under tight deadlines, which necessitate cloud computing implementations, but without sacrificing ease of use.

2 - PyPSA on the Cloud: Easy on-Demand Scaling for Open Energy Models

Soham Garg, AWS, London, United Kingdom, Satheesh Maheswaran

Many real-world energy planning studies require computational power that is beyond the reach of most laptops and desktops. Advanced studies also require running and analyzing large batches of scenarios in parallel. This is challenging for users who do not have access to institutional high performance computing clusters. This talk presents a cloud workflow for the PyPSA energy modelling framework, in the form of ready-to-use templates and infrastructure-as-code, that allows new and advanced PyPSA modellers to run their scenarios in the cloud, using per-hour and on-demand cloud computing. By simplifying access to cloud computing resources, this workflow enables more modellers to push the limits on larger, faster, and more accurate large-scale energy models.

3 - Energy Modeling with Open Data

Austen Sharpe, Catalyst Cooperative, Philadelphia, PA, United States, Christina Gosnell

Catalyst Cooperative created and maintains the Public Utility Data Liberation (PUDL) project to support a variety of decarbonization projects with free and open-source data about the U.S. electricity system. PUDL is used by a variety of users from academics to clean energy developers and advocates. One key use case of PUDL is energy modeling. PUDL is a core data input to several open source energy models including GenX, PyPSA-US and GridPath.

There is a wealth of available data about the energy system in the U.S. but it can be challenging to access and use. Data is published across dozens of websites in disparate challenging formats, there is often a lack of shared keys linking assets and entities and there are consistent gaps or inconsistencies in reporting.

Curating data used for many different models - as well as all of the other use cases for PUDL - presents unique challenges. There are many trade-offs we have to manage when transforming the original data to make it more useful for users. We aim for data that is updated regularly, easy to use, includes long time series, has complete geographic coverage, is clean and free of errors, is as granular as possible and is connected to other datasets. Most raw US datasets are not published with those attributes. While many energy modelers have many shared input data needs, their priorities vary greatly. Catalyst tries to manage these needs by compiling high-value and non-controversial data transformations to benefit all users.

4 - The Impacts of Spatial Scale in Disjoint Generation and Transmission Planning

Kamran Tehrani, Stanford University, Stanford, CA, United States, Inês Azevedo

In restructured electricity markets, transmission planning typically follows a “reactive” approach: generation investment plans are an exogenous input to transmission planning models. This sequential process limits planners from co-optimizing complementary generation and transmission investments. Furthermore, generation planners typically use simplified representations of transmission resolution and power flow as compared to transmission planners. We quantify the impacts of this mismatch in transmission representation within reactive and proactive transmission planning processes using a model of the ERCOT interconnection. Our findings reveal that the economic value of transmission information ranges from 4 to 11% of system costs under business-as-usual scenarios, highlighting the importance of proper characterization of transmission constraints and proactive planning.

5 - Open Modeling with ML: Exploring a Physics-Informed Flow Matching Approach for Accelerated Energy Network Optimization

Kshitiz Khanal, Institute for Transportation Research and Education (NC State University), Raleigh, NC, United States

Machine Learning (ML) techniques have been increasingly adopted and explored in energy modeling, because of the capabilities to support decision-making by modeling complex data-driven systems, and provide a faster throughput compared to legacy modeling techniques. The openness in ML community lends itself to the increasing adoption. This exploratory research contributes to open energy modeling by investigating "Flow Matching" (FM), a novel generative artificial intelligence technique, and test the promise of ML to accelerate power system optimization based on patterns in existing data.

This work focuses on developing an FM model that learns the underlying patterns of efficient power flow from a diverse range of simulated scenarios on standard test systems. The physics-informed loss functions ground the patterns learned from data to reality. The initial results are encouraging, showcasing the FM model's ability to produce near-optimal solutions faster than conventional DC Optimal Power Flow (OPF) solvers. Importantly, the model demonstrates a potential to generalize its predictions in previously unseen extreme conditions, such as significantly increased electricity demand or unexpected generator outages, often maintaining high solution quality and adherence to system constraints.

These findings underscore the potential of Flow Matching and machine learning in general as a useful, data-driven component within the open energy modeling toolkit. This approach could empower researchers and planners with faster, more agile decision-support capabilities, fostering wider participation and innovation in the design and operation of resilient and efficient future energy systems enabled by the openness in machine learning community of practice.

6 - Mosaic: Open-Source Agent-Based Infrastructure Planning

Ruaridh Macdonald, Massachusetts Institute of Technology, Cambridge, MA, United States, yu weng

Recent studies of decarbonized electricity systems have shown the importance of low-emission firm generation in reducing the average cost of electricity, particularly when considering extreme events and interannual variation of variable renewable generation demand. These studies of the value of firm generation have used optimization-based capacity expansion models to determine the optimal design and operation of the electricity grid. While several of these studies have used multi-period optimizations, they did not consider how the ordering of investments or short-term private incentives may lead to higher electricity prices and / or worse grid reliability. This was because optimization-based approaches to this analysis struggle to explore path-dependency effects, heterogenous and imperfect future information, and private interests which are not aligned with public ones.

As an alternative approach, we are developing Mosaic, an agent-based capacity expansion model, to simulate the progression of the energy transition and evaluate the role of different forms of clean firm generation in ensuring a resilient and reliable electricity grid. We believe Mosaic offers new insights into grid investment decisions, as the cost of less insights into energy markets and dispatch decisions than other agent-based grid models. This talk discusses our recent progress and the impact of developing Mosaic as an open-source project.

Optimization and Market Design of Energy Storage in Power Systems

Invited Session

ENRE: Electricity

Chair: Dongwei Zhao, Argonne National Laboratory, Westmont, IL, United States

1 - Price Formation and Long-Term Equilibrium in Future Electricity Markets: the Role of Energy Storage

Audun Botterud, Massachusetts Institute of Technology, Cambridge, MA, United States, Magnus Korpås, Guillaume Tarel

As existing generation resources retire, Variable Renewable Energy (VRE) and Energy Storage (ES) will have an increasingly important impact on the price dynamics in future electricity markets. A key question is whether the expected future dominance of VRE and ES requires a complete rethink of electricity markets or if marginal improvements to existing market designs are sufficient. We use a stylized analytical model based on load duration curves to illustrate price formation, revenue sufficiency, and long-term market equilibrium under the transition towards zero-carbon electricity systems, with a particular focus on the role of ES. We find that energy-only markets with scarcity prices set to the value of lost load may continue to provide adequate incentives for operations and investments after the introduction of VRE and ES. Moreover, ES plays an increasingly important role in price dynamics as thermal plants are pushed out of the competitive equilibrium. If the system reaches a state where flexible generators with non-zero marginal costs are no longer part of the optimal resource mix, our results indicate that equilibrium prices need to directly reflect the capital costs of VRE and ES. Our results raise questions around which cost elements should be allowed in short-term energy market offers, the role of capacity remuneration mechanisms, and the importance of long-term energy contracts in zero-carbon markets dominated by VRE and ES.

2 - Reliability Assessment of Energy Storage as a Transmission Asset

Dongwei Zhao, Argonne National Laboratory, Lemont, IL, United States, Zhi Zhou, David Schloff

Energy storage technologies have been technically proven to be capable of providing transmission services. However, their unique operational constraints as transmission assets and technical complexity present a range of challenges in technical feasibility, economic viability, and regulatory alignment within existing ISO/RTO practices. A research gap exists in the literature and available tools for assessing the reliability contribution of energy storage as a transmission asset, which lays the foundation of cost-benefit assessment of energy storage-based transmission solutions.

This work develops an integrated simulation-based reliability-assessment framework to evaluate the reliability contribution of energy storage as a transmission asset, which is called to provide transmission service when a N-1-1 contingency occurs. The assessment is designed for two deployment scenarios: transmission-asset only and dual use where a storage project may participate in a wholesale market. We define the period when an energy storage project serves as a transmission asset as Transmission Service Period (TSP). In the transmission-asset only scenario, the TSP is the whole 24 hours period. In the dual-use scenario, the TSP period is estimated based on system reliability condition. Outside the TSP, energy storage is allowed market participation, with state-of-charge (SOC) constraints enforced to ensure availability during the TSP. We conduct sensitivity analyses on SOC levels and storage durations to assess their impact on both reliability performance and market revenues. By comparing the two scenarios, we quantify the economic and reliability values of dual-use strategies and offer insights to enhance the value proposition of storage as a transmission asset.

3 - Characterizing Real-Time Electric Vehicle Impacts: Integrated Transportation and Grid Modeling Under Extreme Weather

Siyuan Wang, Argonne National Laboratory, Lemont, IL, United States, YANTAO HUANG

As electric vehicle (EV) adoption increases, the storage capacity provided by these vehicles can enhance the resilience of grid operations. This work focuses on integrating transportation and power distribution grid models to improve urban resilience under extreme weather conditions. We incorporate detailed transportation simulations to account for weather-related delays, road closures, and congestion, while expanding EV charging behavior models to align with grid capabilities. The distribution grid model will be improved to support real-time grid recovery and leverage EVs for grid supports. The dynamic features from model integrations help minimize disruptions and optimize EV resource use for a more resilient infrastructure.

4 - Coupler-Compliant Pcm Chipps: Enabling Dynamic Co-Simulation of Hydropower and Grid Operations

Matija Pavicevic, Argonne National Laboratory, Lemont, IL, United States, Phumthep Bunnak, Stefano Galelli, Sean Turner, Quentin Ploussard

As hydropower's role in grid flexibility grows, the limitations of existing Production Cost Models (PCMs) become increasingly apparent. Traditional PCMs often oversimplify hydropower operations, failing to capture the physical and temporal constraints of water management. To address this, we are developing a high-performance, coupling-compliant PCM module—referred to as a PCM CHiPP (Coupler-Compliant High-Performance Plier)—as part of the HydroCHiPPs project.

The PCM CHiPP is a lightweight, open-source emulator of industry-standard PCM behavior, designed specifically for dynamic coupling with river operations models (ROMs). Built from the PowNet framework, the PCM CHiPP replicates short-term economic dispatch of hydropower units under price, demand, and system constraints. A primary design goal is to expose a well-defined API for two-way communication, enabling the exchange of dispatch targets, reservoir states, and system conditions at user-defined intervals (e.g., hourly, sub-daily).

This modular approach allows the PCM CHiPP to be integrated into coupled simulation environments without the overhead of full production-grade PCM software. The resulting system supports experimentation with synchronization strategies, data exchange frequency, and optimization timing—providing new insights into how ROM-PCM interactions affect dispatch efficiency, revenue potential, and system flexibility.

The PCM CHiPP is being configured for both a synthetic hydropower cascade test system, enabling reproducible benchmarking and publication. Through this work, we aim to provide a scalable tool that lowers the barrier to coupling adoption and helps bridge the gap between power system planning and hydropower reality.

5 - Differentiable Robust Optimization for Electricity Dispatch: a Gradient-Based Framework for Managing Uncertainty

Owen Shen, MIT, Cambridge, MA, United States, Hungpo Chao, Patrick Jaillet, Haihao Lu

Rising uncertainty in power systems—driven by renewable energy integration and extreme weather—challenges the effectiveness of traditional optimal dispatch methods. This paper presents a differentiable robust optimization framework for electricity dispatch with energy storage, leveraging duality theory, optimization theory, and gradient-based methods. The approach offers three key advantages: First, it accommodates time-varying uncertainty sets, allowing a more accurate representation of renewable generation volatility than fixed-set methods. Second, it supports fast re-optimization via warm-starting, enabling responsiveness to real-time forecast updates. Third, it leverages linear programming duality for efficient gradient computation, yielding economically meaningful shadow prices across uncertainty scenarios. A numerical case study illustrates the framework's scalability and adaptability, highlighting its potential to improve grid reliability and economic performance amid increasing uncertainty.

Operations Research and Game-Theoretic Approaches for Sustainable Natural Resource and Energy Systems

Invited Session

ENRE: Natural Resources

Chair: Hyunwoo Lee, Virginia Tech, Blacksburg, VA, 24060, United States

1 - Game-Theoretic Modeling of Insurance Market Dynamics in Wildfire-Prone Regions

Jia Choi, University at Buffalo, Buffalo, NY, United States, Jun Zhuang

California faces increasing wildfire risks, especially in densely populated areas like Los Angeles County. Government regulations, such as premium caps, aim to maintain insurance affordability, but have led insurers to exit high-risk markets, leaving many homeowners uninsured. This study develops a game-theoretic model to examine strategic interactions among regulators, insurers, and homeowners. The model captures decisions related to market participation, regulation intensity, and insurance choices under varying wildfire risks. Using data from LA County, we calibrate payoffs based on insurance profits, regulation costs, and wildfire losses. Results show that overly strict regulation can destabilize the insurance market, while balanced policies with mitigation incentives support both affordability and market stability. The findings offer policy insights to prevent insurance inaccessibility in wildfire-prone areas under climate change.

2 - Optimizing Surveillance and Management of Round Goby Invasion in Lake Champlain

Sabah Bushaj, State University of New York at Plattsburgh, Plattsburgh, NY, United States

The invasive round goby (*Neogobius melanostomus*) is an imminent ecological and economic threat to Lake Champlain, approaching via the Champlain Canal and Richelieu River. With the significant economic impacts of biological invasions escalating, proactive and strategic management is urgently needed. In this study, we propose an integrated simulation-optimization framework explicitly designed to optimize surveillance, prevention, and control efforts within realistic budgetary and logistical constraints. The simulation component of our model provides a spatially explicit representation of round goby dispersal dynamics, integrating critical biological traits such as dispersal rates, reproduction patterns, and survival probabilities, alongside detailed hydrodynamic modeling of the Champlain Canal and Richelieu River. We simulate multiple scenarios representing different levels of infestation risk (low, medium, high) to comprehensively explore potential invasion outcomes. The simulation outputs feed into an optimization model, formulated as a mixed-integer programming problem. The optimization seeks to minimize ecological damage, management costs, and overall resource usage. The decision variables include targeted surveillance locations and frequencies, round goby removal operations, and operational decisions concerning canal lock management. Constraints embedded within the model ensure adherence to practical limitations such as available budgets, labor, and equipment resources. The results from computational experiments provide clear and actionable strategies for resource allocation and management operations, including optimized recommendations for surveillance and removal efforts, and specific operational guidelines for canal lock management. This integrated methodological framework offers a flexible, generalizable approach applicable to managing other invasive species and similar ecological threats in aquatic ecosystems.

3 - Spatial Optimization Models for Width-Constrained Wildlife Corridor Design

Amirreza Saffarian, University of Florida, GAINESVILLE, FL, United States, Jorge Sefair

Human activities are increasingly fragmenting natural habitats, placing many species at risk. This creates an urgent need to preserve biodiversity and maintain ecological connectivity through wildlife corridors. We present two spatial optimization models for corridor design that explicitly incorporate corridor width as a key ecological criterion. The first model minimizes total corridor cost while meeting minimum width requirements, and the second maximizes corridor width under a fixed budget. Together, these models offer a flexible framework for connecting multiple fragmented areas, accommodating both regular and irregularly shaped candidate patches. To improve computational efficiency for the width maximization model, we develop a binary search-based algorithm and introduce a cut separation technique that integrates spatial information with mathematical formulations to generate strong initial bounds on achievable corridor width. We evaluate the models and solution methods on a range of synthetic and real-world landscapes, including a conservation case study focused on maintaining habitat connectivity for the Florida panther.

4 - A Wildfire Propagation Graph-Based Approach for Firebreak Planning in Fire-Prone Landscapes

Denys Yemshanov, Canadian Forest Service, Ontario, ON, Canada, Ning Liu, Eric Neilson, Daniel Thompson, Frank Koch

Firebreaks and fuel treatments are critical means for the reduction of wildfire hazard in fire-prone landscapes. However, the uncertain behaviour of wildfires makes the planning of firebreaks challenging, especially when the available resources are insufficient to treat all locations under wildfire threat. We propose a fire propagation graph-based approach that uses acyclic directed graphs to track the possible spread of wildfires in complex landscapes and estimate the impacts of firebreak placement decisions on the potential burn area at the landscape-level scale. We integrate the fire propagation graph concept into a mixed-integer programming model that allocates firebreaks in a fire-prone landscape. We used this model to compare two firebreak planning strategies. The first strategy reduces the connectivity between forest patches with fuel and minimizes the number of location pairs between which a wildfire could spread in the landscape. The second strategy minimizes the potential burn area in the landscape by tracking the impact of the firebreaks on the fire spread through a set of fire propagation graphs. We compared optimization problems for each strategy with a problem that combines both strategies.

We illustrated the approach with the planning of wildfire mitigation measures in the Red Rock-Prairie Creek area of Canada, a fire-prone forest landscape. The firebreak solutions were able to effectively reduce both the potential burn area and the connectivity between sites with fuel in the landscape. Our solutions help uncover the trade-offs between the different firebreak planning strategies and could assist wildfire mitigation planning in other regions.

Building B Level 2 B206

Modeling the Energy Transition in Africa

Invited Session

ENRE: Energy-Climate

Chair: Erin Baker, Univ of Massachusetts-Amherst, Amherst, MA, United States

1 - An Equitable Energy Transition: Integrating Community Perspectives into Power System Modeling in an Emerging Economy

Faustina Sarfo, University of Massachusetts, Amherst, MA, United States

Ghana faces significant challenges in providing reliable and equitable electricity to its population. This energy crisis, especially in Northern Ghana, has resulted in unreliable power supplies that disproportionately affect marginalized communities, hindering economic growth and quality of life. Our ultimate goal is to integrate community-driven metrics into an energy system model for Ghana, ensuring that energy planning not only addresses technical challenges but also incorporates the needs of marginalized communities. As a first step to parameterizing the model, we will analyze electricity demand data from Northern Ghana to identify blackout periods and estimate latent demand using a statistical model. This will provide insight on how blackouts impact grid performance and offer a clearer understanding of the unmet electricity demand in underserved regions. As a next step, we will develop a version of GenX tailored specifically to Ghana's energy system, focusing on implementing the first metric of reliability-adjusted access. This metric, which combines electricity access with system reliability, will be integrated into GenX to assess energy investment pathways and their potential to improve both grid reliability and equitable access to electricity in rural regions. This will directly contribute to simulating energy system configurations and evaluating investment strategies that prioritize these equity goals. By linking the estimation of latent demand with the implementation of reliability-adjusted access in GenX, the research will help set the stage for future applications that prioritize equity in Ghana's energy transition.

2 - Modelling Political Economy Constraints in Nigeria's Power Sector: Tariff Structures, Subsidies and Investment Decisions

Oladoyin Phillips, Princeton University, Princeton, NJ, United States, Emil Dimanchev, Jesse Jenkins

Regulating the electricity sector in countries in the Global South requires acknowledging the need for a careful balance between political and economic incentives and the market constraints this balance produces. In Nigeria, the resulting policy environment features electricity tariffs that remain below revenue-sufficient levels, contributing to underinvestment in grid capacity and unreliable service. To maintain system functionality, the government provides subsidies that artificially reduce the effective cost of grid electricity for distribution companies (DisCos), enabling them to purchase power at rates below economically sustainable levels. Furthermore, the Service-Based Tariff (SBT) regime was introduced to allow higher tariffs in exchange for improved service quality. However, the combined effects of these measures on cost, reliability, and the energy mix are unclear. This study presents an electricity system equilibrium model that analyses how Nigeria's electricity subsidy regime and SBT structure influence investment and operational decisions by electricity producers and consumers. The model examines the DisCo's investment decisions and allocation of limited grid electricity across feeders and consumer decisions regarding distributed energy technologies—solar PV, batteries, and fossil fuel generators. Sensitivity tests on diesel, solar, and battery costs explore trade-offs in system reliability, affordability, and emissions intensity. These tests also reveal scenarios where grid defection is more likely or where alternative business arrangements involving a mix of on- and off-grid supply may be more appropriate. This approach offers an analytical framework for understanding second-best outcomes under political and financial constraints, supporting context-specific transition pathways for African electricity systems.

3 - Multi-Stage Optimization Models for Cost-Effective Rural Electrification Planning

Ayşe Selin Kocaman, Bilkent University, Ankara, Turkey, Gözde Yazici, Oya Ekin Karasan

Approximately 9% of the global population still lacks access to electricity, with most residing in rural areas. Addressing this challenge requires the careful planning of decentralized energy systems that balance cost, reliability, and scalability. In this study, we develop novel mathematical optimization models to support rural electrification by determining the optimal technology—grid, mini-grid, or off-grid—for each demand point, while simultaneously designing cost-effective grid and mini-grid networks.

We extend these models into a multi-stage framework that captures real-world constraints such as limited budgets and infrastructure rollout timelines, enabling phased implementation. This dynamic approach demonstrates clear advantages in cost and flexibility over static, single-stage planning methods.

Given the scale and complexity of the problem—an extension of the NP-hard k-MST problem—we incorporate advanced solution techniques, including decomposition methods and non-compact, cut-based formulations, to improve computational performance. Numerical experiments on both real-world and synthetic datasets demonstrate the effectiveness and scalability of our models across diverse rural settings.

Our findings provide a rigorous and practical decision-support framework for rural electrification planning. The proposed tools support broader development goals, particularly Sustainable Development Goal 7 and the World Bank's Mission 300 initiative, by enabling cost-efficient and scalable energy access strategies.

4 - Bridging Climate Risk and Grid Resilience in Africa's Energy Transition

Kwame Donkor, University of Washington, Seattle, WA, United States, June Lukuyu

As climate risks intensify and urban populations grow, strengthening the resilience of electricity distribution networks in Sub-Saharan Africa is increasingly urgent. This work presents modeling and statistical analysis approaches to support data-driven, equitable grid planning in resource-constrained contexts, with a focus on Accra, Ghana. We leverage a first-of-its-kind, high-resolution dataset on distribution-level outages and voltage quality in the region to investigate how extreme weather events, including heatwaves and intense rainfall, interact with grid reliability and power quality in Accra. Our results show that climate-vulnerable neighborhoods disproportionately experience long-duration outages and sustained undervoltages, compounding existing socioeconomic risks. By combining statistical analysis, machine learning, and stakeholder engagement, we demonstrate how low-cost sensing and open-source tools can help bridge the data-to-impact gap. This work contributes a replicable framework for identifying priority areas for resilience investment and for modeling how climate and social vulnerabilities intersect with infrastructure weakness. The approaches and insights presented aim to support more adaptive, inclusive energy system planning as the region moves toward electrification, decarbonization, and development goals.

5 - Participatory Policy Analysis of Electric Cooking for Informal Settlements in Kampala, Uganda

Civian Kiki Massa, University of Massachusetts, Amherst, MA, United States, Jessica Kersey

Air pollution from cooking with polluting biomass and fossil fuels causes an estimated 740,000 premature deaths annually in sub-Saharan Africa (SSA). Despite decades of effort, the uptake of transitional cooking fuels, such as liquefied petroleum gas, has been slow in the region. Electric cooking (e-cooking) is emerging as a viable alternative in urban areas due to the availability of grid infrastructure. However, applied research on efficient cooking appliances has largely overlooked the potential of e-cooking for vulnerable urban populations. Informal settlements, home to over 60% of SSA's urban population, disproportionately bear the burdens of polluting cooking fuels.

This study leverages policy benefit analysis modeling to quantify the missed opportunities of not prioritizing informal settlements in efficient e-cooking initiatives. Using data collected through participatory methods, we simulate the impacts of four scenarios of e-cooking uptake. Our analysis quantifies environmental benefits such as avoided emissions, health benefits including prevented premature deaths and averted disability-adjusted life years (DALYs), economic gains from fuel switching, and social benefits like time savings. By comparing these benefits to the costs of implementation, we provide actionable insights for policymakers seeking to balance equity and efficiency in energy transitions. Our findings emphasize the importance of integrating informal settlements into e-cooking strategies, highlighting their potential to advance sustainable development goals while improving the quality of life for underserved communities.

6 - Designing Decentralized Solar Systems in Dust Affected Regions of West Africa

Stewart Isaacs, Massachusetts Institute of Technology, Cambridge, MA, United States, Danielle Wood, Olivier de Weck, Wesley Harris

Decentralized solar energy is a promising strategy to expand modern energy access in rural West Africa. However, in many parts of the region, photovoltaic (PV) power output is reduced by seasonal dust aerosols, which both accumulate on panels (soiling) and attenuate incoming solar radiation. In this work, we develop a data-driven surrogate model to support the design of decentralized PV systems in dusty environments. The model takes as input environmental data such as particulate matter concentration and estimates PV energy generation, soiling losses, and system reliability. We use the model to explore how optimal system parameters—such as panel tilt angle and energy storage capacity—shift when accounting for environmental constraints, reliability, and revenue from energy services. Our findings highlight how dust effects can influence PV system design tradeoffs, and how modeling these effects can guide reliable deployments in under-resourced regions.

Building B Level 2 B207

Operational and Policy Innovations for Modern Healthcare

Invited Session

Health Applications Society

Chair: Liang (Leon) Xu, Singapore Management University, Singapore, Singapore

1 - Developing Health-Aware Built Environments for Personalized Healthcare

Yiwen Dong, Stanford University, Stanford, CA, United States

Our surrounding built environment, traditionally static and inert, is becoming an active partner in healthcare through advances in contactless sensing and artificial intelligence. This work introduces a new research concept of Health-Aware Built Environments (HABE) - spaces equipped with passive monitoring systems (i.e., unobtrusive, non-contact sensors such as vibration, radar, vision sensors) that continuously analyze human-environment interactions to uncover latent disease markers that guides the detection and intervention of personalized health conditions in daily living spaces. HABE captures traditionally hard-to-measure health signals from everyday behaviors, including gradual changes in mobility and sudden shifts in daily activity routines, that often go unnoticed in traditional clinical assessments. HABE enables proactive, precision, and personalized monitoring of various health conditions, such as neuropsychiatric, aging (e.g., Alzheimer's disease, Parkinson's, frailty), and neurodevelopmental (e.g., Autism) conditions. We present a framework for translating these daily behavior (e.g., room transitions, human-environment interactions) into disease markers, demonstrating how buildings can evolve from passive infrastructure to diagnostic agents for personalized healthcare. By bridging artificial intelligence, civil engineering, and clinical medicine, we envision a future where buildings themselves become intelligent allies in preventing and managing diseases, supporting aging in place, and fundamentally transforming our physical spaces into partners in personalized healthcare.

2 - Designing Specialist-Response Policies in Hospital Emergency Departments

Emily Zhu, Texas State University, San Marcos, TX, United States

Emergency department (ED) crowding continues to threaten timely care delivery worldwide. A major contributor to ED delays is the specialist consultation (SC) process, where ED physicians request expert evaluations from off-site specialists. These requests often face significant Request-to-Realization (R2R) delays—time gaps between request and consultation—due to specialists' competing responsibilities. Using data from over one million ED visits across 11 Montreal hospitals, we identify SC delays as a key bottleneck in patient flow, exceeding the impact of lab and imaging delays.

3 - Optimizing Family-Centered Genetic Testing Pricing and Product Portfolio

Ying Cao, Penn State University - Erie, Erie, PA, United States, Xinyu Wei, Yuchen Wang, Xianghui Peng, Victor Prybutok

The importance of a family-centered approach to genetic testing is gaining increasing recognition among healthcare practitioners. Genetic testing results within family units are crucial for selecting newer targeted therapies and prompting relatives to assess their own cancer risks, particularly for genetic disorders such as cancers. Despite these benefits, genetic testing remains underutilized by patients and their families, largely due to cost concerns, a shortage of genetic counselors, and limited or outdated genetics training among some healthcare providers. This study investigates the portfolio design and pricing of family-centered genetic testing product offerings in face of varied family structures and risk profiles. Our research provides recommendations for health service providers to design genetic testing product portfolio that maximizes health benefits for families and addresses the technological scalability.

4 - The "Netflix Model": A New Payment Model for Asymptomatic Disease Management

Huaiyang Zhong, Virginia Tech, Blacksburg, VA, United States

Rising drug prices challenge public payers aiming to expand access to curative therapies without destabilizing budgets. Two types of Subscription-Based Drug Contracts (SBDCs) have emerged to address this. In 2015, Australia adopted a pure subscription model, paying a fixed amount for unlimited hepatitis C treatment. In 2019, Louisiana and Washington launched "modified subscription" deals, paying per prescription up to a cap, after which additional treatment incurred no cost. Despite similar contracts, outcomes varied: Louisiana and Australia saw treatment surges, while Washington did not. This paper uses a game-theoretical model to explain this discrepancy, showing that SBDC effectiveness depends on both contract structure and the population's willingness to engage with screening. SBDCs are most impactful where

traditional outreach fails, as they incentivize identifying and treating hidden demand. We formalize this using a willingness-to-screen (WTS) metric, derive effectiveness thresholds, and calibrate the model with Medicaid data to provide targeted policy guidance.

5 - Reducing Prescription Errors Through Information Interventions: A Field Experiment in Healthcare Operations

Xiaodan Shao, Nanyang Technological University, Singapore, Singapore, Vivek kumar Choudhary, Arnab Majumdar, Burhanuddin Pithawala

Can simple, non-mandatory, and cost-effective informational interventions effectively reduce prescription errors, given that mandatory systems often fail due to high overrides by doctors? Do such interventions facilitate proactive learning or merely promote reactive corrections? We address these questions by examining major drug-to-drug interaction (DDI) errors in prescribing, a critical patient safety issue causing significant harm. Using a difference-in-differences model, we analyze data from a randomized field experiment involving 2.81 million prescriptions by ~1,700 doctors in India. Doctors were randomized into a treatment group receiving non-mandatory real-time informational interventions about potential errors or a control group without interventions. Results show that the treatment group prescribed ~8.6% fewer errors compared to controls, potentially reducing hospitalization costs by US\$4.8 million and saving an estimated 134 lives annually. Interestingly, doctors exposed to the intervention appear to effectively learn from the interventions, resulting in proactive avoidance of prescribing errors rather than mere corrections. Initially, error reduction is driven by immediate corrections, but sustained improvements result from proactive avoidance facilitated by learning. The effect is more pronounced among doctors with higher workloads. We find that the effectiveness of interventions remains consistent and does not negatively impact productivity or care quality. Managers can strategically utilize heterogeneity in treatment effects to target specific doctors and address errors more effectively. The feasibility of proactive learning reduces the reliance on continuous digital support, particularly benefiting healthcare systems in regions undergoing digitalization with limited internet connectivity.

Distributionally Robust Optimization and Machine Learning

Invited Session

OPT: Machine Learning

Chair: Weijun Xie, Georgia Institute of Technology, Atlanta, GA, United States

Co-Chair: Siyuan Chen, Georgia Institute of Technology, Atlanta, GA, 30332, United States

1 - Data-Driven Conditional Optimization

Jonathan Li, Telfer School of Management, University of Ottawa, Ottawa, ON, Canada, Qinyu Wu

This talk introduces a distributionally robust framework for conditional optimization, aimed at addressing emerging challenges such as data scarcity, bias, and distribution shifts—issues commonly encountered in modern machine learning applications.

2 - Towards Learning An Optimal Robust Assortment

Miao Lu, Stanford University, Stanford, CA, United States, Yuxuan Han, Han Zhong, Zhengyuan Zhou, Jose Blanchet

Assortment optimization is a fundamental challenge in modern retail and recommendation systems, where the goal is to select a subset of products that maximizes expected revenue under complex customer choice behaviors. While recent advances in data-driven methods have leveraged historical data to learn and optimize assortments, these approaches typically rely on strong assumptions -- namely, the stability of customer preferences and the correctness of underlying choice models. However, such assumptions frequently break in real-world scenarios due to preference shifts and model misspecification, leading to poor generalization and revenue loss. Motivated by this limitation, we propose a robust framework for data-driven assortment optimization that accounts for potential distributional shifts in customer choice behavior. Our approach models uncertainty around a nominal choice model that generates observational data and seeks to maximize worst-case expected revenue. We first establish the computational tractability of robust assortment planning when the nominal model is known, then advance to the data-driven setting, where we design statistically optimal algorithms that minimize data requirements while maintaining robustness. Our theoretical analysis provides both upper bounds and matching lower bounds on the sample complexity, offering theoretical guarantees for robust generalization. Notably, we uncover and identify the notion of "robust item-wise coverage" as the minimal data requirement to enable sample-efficient robust assortment learning. Our work bridges the gap between robustness and statistical efficiency in assortment learning, contributing new insights and tools for reliable decision-making under uncertainty.

3 - Mixed-Feature Logistic Regression Robust to Distribution Shifts

Qingshi Sun, University of Southern California, Los Angeles, CA, United States, Nathan Justin, Andres Gomez, Phebe Vayanos

Logistic regression models are widely used in the social and behavioral sciences and in high-stakes domains, due to their simplicity and interpretability properties. At the same time, such domains are permeated by distribution shifts, where the distribution generating the data changes between training and deployment. In this paper, we study a distributionally robust logistic regression problem that seeks the model that will perform best against adversarial realizations of the data distribution drawn from a suitably constructed Wasserstein ambiguity set. Our model and solution approach differ from prior work in that we can capture settings where the likelihood of distribution shifts can vary across features, significantly broadening the applicability of our model relative to the state-of-the-art. We propose a graph-based solution approach that can be integrated into off-the-shelf optimization solvers. We evaluate the performance of our model and algorithms on numerous publicly available datasets. Our solution achieves a 408x speed-up relative to the state-of-the-art. Additionally, compared to the state-of-the-art, our model reduces average calibration error by up to 36.19% and worst-case calibration error by up to 41.70%, while increasing the average area under the ROC curve (AUC) by up to 18.02% and worst-case AUC by up to 48.37%.

4 - Finite-Adaptability via Explicit Partition

Zolykha Rezaei, Texas Tech University, Lubbock, TX, United States, Ningji Wei, Eojin Han

In many practical scenarios—especially those involving sequential decision making—professionals prefer policies that are not only interpretable but also straightforward to implement. In this research, we explore the concept of finite adaptability to construct robust optimization policies under uncertainty. More specifically, we address a general setting where uncertainty affects both the objective function and the constraints within the model. Our aim is to construct policies by partitioning the uncertainty set and assigning a contingent decision to each segment.

To solve the resulting robust optimization problem, we propose both exact and approximation methods. The exact methods include Benders' decomposition and dualization techniques for linear models. To enhance scalability and effective partition learning, we also develop approximation methods based on machine learning techniques such as support vector machines (SVMs) and decision trees.

5 - A Single-Loop First-Order Method for Robust Optimization

Manru Zong, The University of Hong Kong, Hong Kong, Hong Kong

Robust optimization is a powerful paradigm for decision-making under uncertainty. However, existing algorithms for robust optimization do not scale well, hindering its applications to modern large-scale decision problems. To address this challenge, we adopt the max-min-max framework recently proposed by Tu, Chen and Yue, and devise a single-loop first-order method, which is particularly suitable for large-scale robust optimization problems. We prove that our method enjoys a convergence rate of $O(K^{-0.5})$ for general non-smooth convex objective and constraint functions. We also prove that the rate can be improved to $O(K^{-1})$ under an additional smoothness or strong convexity assumption. Numerical experiments show that our method achieves a superior performance against existing approaches.

6 - Distributionally Robust Optimization Through the Lens of Submodularity

Karthik Natarajan, Singapore University of Technology and Design, Singapore, Singapore, Arjun Ramachandra, Divya Padmanabhan

We introduce a submodular ambiguity set and showcase its expressive power in modeling both discrete and continuous uncertainty. With discrete uncertainty, we show that a class of distributionally robust optimization problems is solvable in polynomial time and with continuous uncertainty, we show that it is solvable approximately up to an additive error in pseudo-polynomial time. In special cases, these problems can be solved as compact linear and semidefinite programs. We highlight the usefulness of these ambiguity sets particularly in optimization problems involving fairness criterion.

1 - Raising the Rainbow Flag: Impact of Lgbtq+ Safety Cues on Service Provider Selection**Priyank Arora, University of South Carolina, Columbia, SC, United States, Mert Cetin, Dorothee Honhon**

In practice, several service systems are increasingly encouraging the use of LGBTQ+ safety cues from service providers to clients—for example, the use of rainbow flag stickers next to the service providers' names or pictures. As such, LGBTQ+ safety cues from service providers can help convey (1) LGBTQ+ Allyship: the service provider is an ally of the LGBTQ+ community, demonstrating support for LGBTQ+ rights and equality, and/or (2) Safe and Inclusive Space: the service provider is committed to providing a welcoming, non-judgmental, and affirming environment for LGBTQ+ clients. Intrigued by this emerging trend and inspired by calls to study the operations of inclusive service systems, we undertake this study to understand the effect of LGBTQ+ safety cues on the service provider selection process of clients, both from the LGBTQ+ community and the non-LGBTQ+ community. Specifically, our study aims to investigate whether such an LGBTQ+ safety cue given by the service provider is viewed positively or negatively by clients in their selection process. We also investigate how the effect of this cue on the selection process varies by the characteristics of the clients and the attributes of the service providers. Our findings provide insights into the decision-making process of the LGBTQ+ community, which can help organizations (re)design their operational practices and processes to improve equity and inclusion.

2 - Mitigation Planning for Community Resilience: a Two-Stage Robust Optimization Approach**Tasnim Faiz, University of Maryland, College Park, MD, United States, Kenneth Harrison**

Following high-impact hazard events, communities experience failures in their built environment, e.g., critical infrastructure and buildings. Damaged residential buildings cause injuries, fatalities, displacements, and high recovery costs, whereas damaged critical infrastructure reduces access to lifeline services. Proactive mitigation actions for the built environment can help avoid the adverse effects of hazards, reduce the risk associated with rare high-impact events, and improve community resilience against hazards. However, the complex interdependencies among a community's infrastructures and social functions, different resilience metrics, limited budget, and uncertainty associated with hazard events make mitigation planning challenging. A two-stage robust optimization framework is developed to address the uncertainties and the risk associated with rare high-impact events. Hazard uncertainty is defined by an ambiguity set, which facilitates tuning the degree of risk aversion when constructing high-impact hazard scenarios. The framework iteratively generates the worst-case hazard scenario and updates the mitigation decisions to minimize the resulting recovery and societal costs. A case study is presented to illustrate the benefit of the framework in developing alternative mitigation strategies for different levels of risk aversion to improve community resilience.

3 - Fair Resource Allocation Under Uncertain Utility Perception**Samuel Rodriguez, University of Oklahoma, Norman, OK, United States, Andres Gonzalez Huertas, Daniel Cabrera, Camilo Gomez**

Fair resource allocation in networked systems—such as energy grids, water infrastructure, or interdependent infrastructure network systems—hinges on how users derive value from the resources they receive. Yet when user preferences are uncertain or only partially observed, standard fairness assumptions may fail, raising concerns about the robustness of equity-driven allocation strategies. This paper examines the impact of utility function uncertainty within the Proportional Fairness framework—a widely adopted scheme that balances efficiency and fairness through logarithmic utility aggregation. We study two representative utility models: linear functions with constant marginal returns and power functions that capture diminishing returns. While linear utilities are structurally stable under uncertainty, power utilities are not, revealing vulnerabilities in fairness outcomes. To address this, we propose a Two-Stage Stochastic Programming approach that integrates uncertainty directly into the allocation process without abandoning fairness as a guiding principle. We demonstrate the method through a case study of Shelby County, TN, modeling the interdependent gas, electric power, and water networks. While the physical infrastructure remains fixed, variation in perceived utility—shaped by social vulnerability—is introduced as a stochastic element. Our results show how uncertainty reshapes allocation behavior, especially under scarcity, and provide both theoretical clarity and computational tools for practitioners seeking resilient and equitable resource distribution in complex networked environments.

4 - Saving Lives: Data-Driven Optimization in Animal Shelters**Qiuxia Chen, The University of Texas at Dallas, Richardson, TX, United States, Elena Katok, Ernan Haruvy**

Each year, an estimated 390,000 dogs are euthanized in the United States due to resource constraints at animal shelters. This study aims to improve live release rates by enhancing operational efficiency through data-driven decision-making. Recognizing the heterogeneity in shelter dog populations—where different conditions warrant different optimal lengths of stay—we address a critical gap in existing queuing models, which typically assume homogeneous service populations. We propose a four-step methodological framework that integrates queuing theory, discriminant analysis, survival analysis, and optimization to tackle the central operational challenge facing shelters: maximizing the live release rate while adhering to capacity constraints. Our model is built on 12 years of intake and outcome data from a large municipal animal shelter, encompassing over 240,000 individual records. The data include detailed information on animal characteristics, shelter conditions, and outcomes. Implementation of our model in 2024 led to a 27% increase in the shelter's live release rate. We project that this improvement can translate to saving between 1,400 and 1,800 dogs annually. These findings demonstrate the potential of operational research to generate meaningful and scalable impact in animal welfare.

5 - Community Operational Research: a 50-Year Retrospective and Prospective Analysis**Michael Johnson, University of Massachusetts Boston, Boston, MA, United States, Maria Pache de Athayde, Namesh Killemsetty**

This paper examines the evolution of Community Operational Research (COR) over the past 50 years, analyzing its methodologies, contributions to practice, and current research opportunities. Using a systematic analysis, we review over 800 scholarly articles according to academic disciplines, application areas, analytical approaches, geographies, characteristics associated with community-engaged research and, where possible, author characteristics. We identify key developments in analytic tools areas such as problem structuring methods, optimization, stochastic modeling, and data analytics, and assess COR's real-world impact in fields like housing, transportation, and environmental sustainability. We highlight the increasing diversity of actors engaged in COR. We discuss contemporary trends in community-engaged operations research and analytics that may or may not be explicitly associated with COR. By analyzing open problems and future directions, we aim to bridge the gap between theoretical advances and the needs of underserved communities.

1 - The Impact of Experience on Managerial Stints: Head-Coach Firing Versus Retiring in The National Football League 1970 through 2023

Michael Lapre, Vanderbilt University, Nashville, TN, United States, Zoe Segal

We study the impact of success and failure experience on the duration of managerial stints for head coaches in the modern era of the National Football League (NFL). We distinguish between stints ending with the firing of a head coach versus a head coach choosing voluntary retirement. From 1970 through 2023, excluding interim head coaches who only coached the latter part of a season, our dataset includes 264 head coaches representing 370 managerial stints. Using survival-analysis methods, we find that experience and NFL-specific control variables impact firing versus retiring differently.

2 - Return on Investment in Collegiate Athletics

Mike Gordon, Virginia Tech, Blacksburg, VA, United States

This study examines the operational efficiency of collegiate athletic departments by analyzing comprehensive financial data from public NCAA institutions. We investigate revenue generation sources, such as ticket sales and student fees, alongside expense categories including athletic student aid, medical support, and severance payments to terminated coaching staff. We specifically address the financial implications of athletic department debt levels and the associated servicing costs. A central focus is the economic impact of football programs, considering their operational scale and revenue potential across competitive divisions. Our findings provide valuable insights for athletic administrators, university leadership, and policymakers seeking to optimize resource allocation and enhance financial sustainability in collegiate athletics.

3 - Surviving NFL Survivor

Michael Gorman, University of Dayton, Dayton, OH, United States

NFL Survivor pools are a popular gambling game in which participants pick a single game per week, and if successful, the participant survives, and if not, the entrant is out. We use a combination of prediction methods, risk reduction, optimization and future discounting to improve outcomes in the popular pool game. We test the prediction and selection models over 19 NFL seasons (2006-2024) and find improved prediction, coupled with risk avoidance and appropriate future discounting leads to improved expected survival rates. Because of the high upset rates inherent in NFL games, portfolio strategies among multiple entries are explored to achieve reliable performance.

4 - Impact of Format Changes to the Uefa Champions League

Stephen Hill, Samford University, Birmingham, AL, United States

In this work we explore the impact of the recent changes to the format of the UEFA Champions League. We examine the competitive balance implications and also consider alternatives.

Recent Advancements in Optimization under Uncertainty with Theory and Applications

Invited Session

OPT: Optimization Under Uncertainty

Chair: Beste Basciftci, Tippie College of Business, University of Iowa, Iowa City, IA, United States

1 - Interpretable Vaccine Administration and Inventory Replenishment Policies via Smooth-In-Expectation Decision Rules

Merve Bodur, University of Edinburgh, Edinburgh, United Kingdom, Zoha Sherkat Masoumi, Jim Luedtke

The effective management of vaccine vials and inventory is imperative for ensuring widespread immunization coverage. We aim to address the challenges associated with this problem, including the need for interpretable policies. We propose a multistage stochastic programming model, which offers flexibility to accommodate various operational aspects such as patient queues, clinic early closure considerations, and the requirement to serve every patient until exhausting vaccine inventory. For developing interpretable policies, we employ smooth-in-expectation decision rules, a recently proposed approach for multistage stochastic programs with mixed-integer recourse decisions and very many stages (e.g., hundreds). Leveraging these decision rules, we formulate and optimize the vaccine administration policies via a problem-specific flowchart design, alongside vial ordering decisions, facilitating interpretability and adaptability in real-world healthcare settings. We implement a batch stochastic gradient descent algorithm to solve the optimization problem, where for the initialization step we use the solution of a two-stage stochastic programming model we propose as an approximation to the multistage problem. Through extensive numerical experiments, we demonstrate the efficiency of the proposed approach and highlight the efficacy of various policies, including those considering patient queues.

2 - Distributionally Robust Optimization with Multimodal Decision-Dependent Ambiguity Sets

Beste Basciftci, Tippie College of Business, University of Iowa, Iowa City, IA, United States, Xian Yu

We consider a two-stage distributionally robust optimization (DRO) model with multimodal uncertainty, where both the mode probabilities and uncertainty distributions could be affected by the first-stage decisions. To address this setting, we propose a generic framework by introducing a phi-divergence based ambiguity set to characterize the decision-dependent mode probabilities and further consider both moment-based and Wasserstein distance-based ambiguity sets to characterize the uncertainty distribution under each mode. We identify two special phi-divergence examples (variation distance and χ^2 -distance) and provide specific forms of decision dependence relationships under which we can derive tractable reformulations. Furthermore, we investigate the benefits of considering multimodality in a DRO model compared to a single-modal counterpart through an analytical analysis. Additionally, we develop a separation-based decomposition algorithm to solve the resulting multimodal decision-dependent DRO models with finite convergence and optimality guarantee under certain settings. We provide a detailed computational study over two example problem settings, the facility location problem and shipment planning problem with pricing, to illustrate our results, which demonstrate that omission of multimodality or decision-dependent uncertainties within DRO frameworks result in inadequately performing solutions with worse in-sample and out-of-sample performances under various settings. We further demonstrate the speed-ups obtained by the solution algorithm against the off-the-shelf solver over various instances.

3 - Distributionally Fair Two-Stage Stochastic Programming by Bilevel Optimization

Yutian He, University of Iowa, Iowa City, IA, United States, Beste Basciftci, Qihang Lin

Two-stage stochastic programming (TSSP) is a fundamental framework for decision-making under uncertainty, where a first-stage decision is made before uncertainty is realized, followed by scenario-dependent second-stage decisions. While most TSSP literature focuses on cost minimization, fairness considerations in decision-making have largely been overlooked. Recently, Ye et al (2024) studied a one-stage stochastic program subject to a distributional fairness constraint, but similar development under the two-stage setting is still unavailable. In this work, we propose two models of TSSP under distributional fairness objective: one where the first- and second-stage decision-makers collaborate to ensure fairness, and another where only the first-stage decision-maker wants to ensure fairness, while the second-stage decision-maker only aims at minimizing the cost. To solve these models, we approximate the expectations by sample average and then propose reformulations resulting in mixed integer convex programs under certain assumptions. We further develop methods for finding computationally efficient lower bounds and introduce algorithmic approaches leveraging difference-of-convex programming reformulations to solve our problems effectively over large-scale instances. We provide case studies over sample problem settings, illustrating the value of the proposed approach and benefits of the proposed reformulations and solution algorithms.

4 - Contextual Stochastic Optimization for Omnichannel Multi-Courier Order Fulfillment Under Delivery Time Uncertainty

Tinghan Ye, Georgia Institute of Technology, Atlanta, GA, United States, Sikai Cheng, Amira Hijazi, Pascal Van Hentenryck

The paper studies a large-scale order fulfillment problem for a leading e-commerce company in the United States. The challenge involves selecting fulfillment centers and shipping carriers with observational data only to efficiently process orders from a vast network of physical stores and warehouses. The company's current practice relies on heuristic rules that choose the cheapest fulfillment and shipping options for each unit, without considering opportunities for batching items or the reliability of carriers in meeting expected delivery dates. The paper develops a data-driven Contextual Stochastic Optimization (CSO) framework that integrates distributional forecasts of delivery time deviations with stochastic and robust order fulfillment optimization models. The framework optimizes the selection of fulfillment centers and carriers,

accounting for item consolidation and delivery time uncertainty. Validated on a real-world data set containing tens of thousands of products, each with hundreds to thousands of fulfillment options, the proposed CSO framework significantly enhances the accuracy of meeting customer-expected delivery dates compared to current practices. It provides a flexible balance between reducing fulfillment costs and managing delivery time deviation risks, emphasizing the importance of contextual information and distributional forecasts in order fulfillment. This is the first paper that studies the omnichannel multi-courier order fulfillment problem with delivery time uncertainty through the lens of contextual optimization, fusing machine learning and optimization. The results provide actionable insights for e-commerce companies and online retailers to enhance service quality and customer satisfaction through efficient order fulfillment strategies that accounts for delivery time uncertainty.

5 - Distributionally Robust Optimization for Chemotherapy Scheduling Under Asymmetric and Multi-Modal Uncertainty

Zoe Zhu, The Ohio State University, Columbus, OH, United States, Xian Yu, Yu-Li Huang

We consider a real-world chemotherapy scheduling problem, where we need to design different appointment durations that can accommodate various patient types. From Mayo Clinic's real data, we observe that most patients' appointment durations are asymmetric (e.g., shorter durations tend to have a longer right tail). To address this, we consider a two-stage distributionally robust optimization (DRO) model under asymmetric and multi-modal uncertainty, where the overall ambiguity set is a mixture of two components. In the first layer, we use a variation-distance-based ambiguity set to capture the ambiguity on the mode probabilities. In the second layer, we consider a moment-based ambiguity set on the distribution in each mode, which includes a second-order partitioned statistics (semivariance) to account for the asymmetry in the random treatment duration distribution. We derive a closed-form expression for the worst-case expected cost and propose an efficient algorithm that can obtain a near-optimal solution in a quick fashion. Through numerical experiments based on both synthetic dataset and Mayo Clinic's real data, we illustrate the effectiveness of our approach and the benefits obtained by incorporating asymmetry information into the DRO formulation.

Network Optimization Algorithms for Societal Applications

Invited Session

OPT: Network Optimization

Chair: David Shmoys, Cornell University, Ithaca, NY, United States

1 - Electrification of Heavy-Duty Vehicles: Challenges and New Algorithmic Insights

Haripriya Pulyassary, Cornell University, Ithaca, NY, United States, David Shmoys, Manxi Wu

While the adoption of electric vehicles (EV) offers substantial environmental benefits, it also introduces new challenges in vehicle routing due to range anxiety, long charging times, and sparse charging infrastructure. In this work, we approach EV routing through the lens of network flow theory. We begin with the analogs of three classical network flow problems: the problem of optimally routing a single EV, the maximum EV flow problem, and the minimum-cost EV flow problem. While these problems are NP-hard in the general case, we identify conditions under which they can be solved in polynomial time, and give exact, polynomial-time algorithms for this setting.

We then consider fleet electrification in long-distance logistics under various recharging modes. To model these, we introduce a general flow-based formulation defined over a charge-and-time augmented network. Due to the density of this network, directly solving the full integer program is impractical. Instead, we propose a variant of dynamic discretization discovery that significantly improves computational time. We also apply these methods in an empirical study of an instance constructed from real-world data.

2 - Leximin Fair Kidney Matching with Match Success Probabilities

Claire Chang, Cornell University, Ithaca, NY, United States, David Shmoys

The kidney matching process is critical for improving patient survival, fair access, and overall transplant success. With donor kidneys in short supply and high demand, the focus in many kidney matching algorithms is to maximize the number of exchanges. However, this convention disadvantages hard-to-match pairs (possibly due to sensitized patients with high antibody levels), many of whom may compete for a desirable donor. Furthermore, different exchanges have different probabilities of success based on factors like compatibility between patient-donor pairs and match rejection rates. Pre-existing work proposes a randomized algorithm that constructs a lottery over maximum cardinality matchings in order to optimize for the welfare of individual patient-donor pairs—that is, the leximin probability that any pair is included in a matching. Leveraging the Edmonds-Gallai decomposition, we exactly characterize the maximin coverage probability and present a simpler method for computing it. We also extend prior work to account for success probability of matches, and construct a lottery over just maximum-weight maximum-cardinality maximum weight matchings. Finally, we describe the Pareto frontier between matchings maximizing weight and cardinality. To better balance between the utilitarian and maximin objectives, we examine not only the leximin fairness objective, but also Nash social welfare as our metric for optimal lotteries.

3 - Fair Division Among Couples and Small Groups

Hannane Yaghoubzade, Cornell University, Ithaca, NY, United States, Paul Goelz

We study the fair allocation of indivisible goods across groups of agents, where each agent fully enjoys all goods allocated to their group.

We focus on groups of two couples and other groups of small size.

For two couples, an EF1 allocation¹,---\,one in which all agents find their group's bundle no worse than the other group's, up to one good\,---\,always exists and can be found efficiently.

For three and more couples EF1 allocations need not exist.

Turning to proportionality, we show that, whenever groups have size at most k , a PROP k allocation exists and can be found efficiently.

In fact, our algorithm additionally guarantees (fractional) Pareto optimality, and PROP1 to the first agent in each group, PROP2 to the second, etc., for an arbitrary agent ordering.

In special cases, we show that there are $\text{propone}\{\}$ allocations for any number of couples.

4 - Collective Communication in Data Centers via Multicommodity Flow

David Shmoys, Cornell University, Ithaca, NY, United States

Data centers today depend on a suite of collective communication protocols to distribute computation and aggregate results over large networks of GPUs. These protocols are typically designed based on simple structures that seek to achieve optimal latency in communication, while making effective use of the bandwidth limitations of the network. We present an approach to the automated design of these collective communication protocols based on multicommodity flow formulations, which therefore allow the design of protocols tailored to the specifics of the underlying network architecture, and can both achieve provable optimal latency, as well as optimizing other important metrics related to overall bandwidth utilization.

5 - Accelerating Decomposition Methods for Multicommodity Flow with Applications to Data Center Routing

Ricky Shapley, Cornell University, Ithaca, NY, United States

Multicommodity flow formulations can be used to generate effective collective communication primitives in GPU networks commonly used for data centers. These formulations are often at a scale that pose significant challenges for their solution. We introduce a number of significant advances in techniques for their efficient solution, including a technique that exploits the inherent symmetries in the architecture of the GPU networks to accelerate typical Dantzig-Wolfe style decomposition methods, coupled with insights that allow LP formulations to yield step-based routing solutions more commonly associated with integer programming formulations.

Applications of Convex Optimization to Nonconvex Problems (part II)

Invited Session

OPT: Linear and Conic Optimization

Chair: Benjamin Grimmer, Johns Hopkins University, Baltimore, MD, United States

Co-Chair: Alex Wang, Purdue University, West Lafayette, IN, United States

Co-Chair: Kevin Shu, California Institute of Technology, Pasadena, CA, United States

1 - A Subgame Perfect Gradient Method**Alex Wang, Purdue University, West Lafayette, IN, United States, Benjamin Grimmer, Kevin Shu**

Optimization algorithm design has historically been concerned with worst-case a priori convergence rates. That is, convergence rates that can be guaranteed at the outset, before any information is learned about the problem instance. In the setting of unconstrained smooth convex optimization, the Optimized Gradient Method (OGM) achieves the optimal such convergence rate and is minimax optimal. In this talk, we introduce a stronger notion of optimality that requires a method to give optimal dynamic guarantees by optimally exploiting any “non-adversarialness” in the first-order oracle’s reported information. We then present a new first-order method achieving this notion of optimality: the Subgame Perfect Gradient Method (SPGM). SPGM is a refinement of OGM where the update rule is dynamically computed at runtime and can be implemented with minimal computational and storage overhead in each iteration. This talk is based on joint work with Benjamin Grimmer and Kevin Shu.

2 - Towards the Semidefinite Representability of Continuous Quadratic Submodular Minimization with Applications To Moment Problems**Samuel Burer, University of Iowa, Iowa City, IA, United States, Karthik Natarajan**

We discuss progress towards approximating continuous quadratic submodular minimization with bounds using semidefinite programming. We investigate two related moment problems arising in distributionally robust optimization and the computation of covariance bounds.

3 - Lagrangian Dual with Zero Duality Gap that Admits Decomposition**Santanu Dey, ISyE Georgia Tech, Atlanta, GA, United States**

For non-convex optimization problems with block structures and coupling constraints, on dualizing the coupling constraints the resulting Lagrangian relaxation becomes decomposable into blocks. However, the resulting Lagrangian dual can have non-zero duality gap due to the inherent non-convexity. In this talk, we propose a reformulation of the problem by adding redundant constraints, such that the Lagrangian dual obtained by dualizing the coupling constraints and the redundant constraints has zero duality gap and is decomposable into blocks. Joint work with Diego Cifuentes, Jingye Xu.

4 - Performance Estimation for Hölder Smooth Functions**Aaron Zoll, Johns Hopkins University, Baltimore, MD, United States, Benjamin Grimmer**

The minimization of Hölder smooth convex functions provides a family of problems interpolating from smooth to nonsmooth Lipschitz. This has proven to be a fruitful model for the design of universal, adaptive algorithms.

In this talk, we extend recent advances in computer-assisted design for first-order optimization over structured functions—known as Performance Estimation Problems (PEP)—to apply to Hölder smooth functions. We derive new “interpolation theorems” for Hölder smooth functions, enabling the computation of the worst-case performance of any proposed fixed stepsize first-order method (up to a small constant factor, approximately 1.2). This new theory is based on characterizations of “approximate cocoercivity” for associated tolerance parameters ϵ . As an application of this new PEP machinery, we identify new best-known methods for Hölder smooth minimization (requiring careful selection of both stepsizes and tolerances ϵ), improving on prior worst-case guarantees by a constant factor.

1 - Funding the Real Deal: Dynamic Moral Hazard with Adverse Selection**Izak Duenyas, University of Michigan-Ann Arbor, Ann Arbor, MI, United States, Feng Tian, Feifan Zhang, Peng Sun**

We study dynamic contracts to incentivize agents with private effort and cost information to generate Poisson breakthroughs. The principal offers a contract menu, inducing self-selection. We characterize optimal contracts under two agent types, revealing simple linear and one-switch structures, and provide a computationally efficient method to construct the full menu.

2 - Right to Repair and Competition in Durable Goods Markets**Cungen Zhu, Tongji University, Shanghai, China, People's Republic of, Luyi Yang, Chen Jin**

The right-to-repair movement advocates for stricter legislation that would require manufacturers of durable goods to facilitate independent repair. It is commonly believed that stronger repair laws would promote market competition—thereby benefiting consumers—and reduce e-waste, thereby protecting the environment. This paper builds a durable goods duopoly model to examine the economic and environmental implications of right-to-repair legislation. We find that when manufacturer competition is intense owing to limited product differentiation, tightening repair laws can further intensify competition and increase consumer surplus. However, when manufacturer competition is mild in a market of highly differentiated products, tightening repair laws can soften competition and hurt consumers. This suggests a polarization effect of strengthening right-to-repair legislation: it may increase competition when it is already strong but dampen competition when it is weak. In the former case, consumers may rush to replace their used products with new ones, which shortens the effective product lifespan and generates more e-waste. Overall, right-to-repair legislation can create a win-win situation that benefits both consumers and the environment, but this intended outcome is achieved in an unintended way: consumers are better off not through more affordable repair but through cheaper products, whereas the reduced environmental impact does not stem from less e-waste but from the use of newer products. Strikingly, tightening repair laws can lead to a lose-lose outcome for both consumers and the environment when they result in widespread availability and use of repair, only to benefit manufacturers by helping them escape the prisoner’s dilemma and thus increase profit.

3 - Dynamic Resource Allocation in Urban Search and Rescue Operations**Huiyin Ouyang, The University of Hong Kong, Hong Kong, Hong Kong, Zheqi Zhang, Sukriye Nilay Argon, Serhan Ziya**

We address resource allocation for urban search and rescue during disasters, focusing on deploying limited assets like helicopters across regions with varying population densities, distances, and rescue deadlines. The problem is modeled as an optimization of waiting and unmet request costs in a multi-class clearing system with deadlines.

Using a Markov decision process for a single resource and two request classes, we derive an optimal switching-curve policy. This insight informs a state-dependent heuristic for multiple resources and classes, which demonstrates near-optimal performance in numerical studies. A simulation based on Hurricane Harvey in 2017 validates the approach, showcasing its effectiveness in improving disaster response.

4 - Optimal Pricing for Queueing Systems with Loss-Averse Customers

Hongfan(Kevin) Chen, The Chinese University of Hong Kong, Shatin, China, People's Republic of, Jian Cao, Junfei Huang, Yongjiang Guo

We consider a single-server queueing system with uncertain service rate, in which customers have either disappointment-based loss-averse (DLA) or regret-based loss-averse (RLA) behavior. We explore the implications of DLA and RLA behaviors in terms of customers' decisions, the system manager's pricing strategies and other system metrics. We further emphasize the differences in these implications. We respectively consider the state-independent and state-dependent models to capture customers' DLA behavior and RLA behavior. We build a queueing game to first analyze customers' equilibrium decisions, and then investigate the system manager's pricing strategies from the perspectives of revenue and social welfare maximization. Our main findings are as follows. Given that customers' DLA behavior discourages customers from joining the queue, common intuition suggests that the manager should reduce the price to attract more customers. However, we observe that the revenue-optimal price may actually rise as customers' DLA level increases. In contrast, we demonstrate that RLA behavior has no impact on the system manager's pricing strategies in the context of revenue maximization, despite that RLA customers experience dis-utilities. From a welfare maximization perspective, in the presence of DLA and RLA behaviors, we demonstrate that interestingly, there may be no efficiency loss when the system manager implements the revenue-maximization pricing decision. Compared to revenue maximization, the system manager should consistently raise prices to mitigate the effects of customers' loss aversion. In a queueing system, it is crucial for the system manager to accurately identify the customers' loss aversion behaviors when determining prices.

5 - Fleet Sizing and Rebalancing in Free-Floating Bike-Sharing Systems

Jun Luo, Shanghai Jiao Tong University, Shanghai, China, People's Republic of, Hang Guo, Jiheng Zhang

Free-floating bike-sharing systems, widely adopted by operators such as Hellobike and Meituan Bike due to their great flexibility to users, present unique challenges in fleet sizing and rebalancing due to the spatial distribution of bicycles affecting user pickup behavior. We model these systems as load-dependent closed queueing networks, capturing spatial features through an explicit load-dependent form that reflects the relationship between bicycle density and user willingness-to-walk. Given the system's complexity, we apply fluid approximation techniques to develop a tractable optimization framework and propose two rebalancing policies: S-policy relocating bicycles to achieve a target system state, and Q-policy relocating a predetermined number depending on availability of bicycles from congested to shortage regions. Both policies are not only practical for real-world implementation but also asymptotic optimal under a large-market scaling regime. Our extensive simulation experiments demonstrate the superior performance of these policies compared to alternative approaches, confirming their effectiveness in maintaining appropriate bicycle distribution while minimizing operational costs across various system configurations.

A Conversation on Health Equity Research in 2025

Panel Session

Health Applications Society

Co-Chair: Karen Hicklin, Icahn School of Medicine at Mount Sinai, New York, NY, 10029, United States

1 - Moderator Panelist

Jennifer Lobo, University of Virginia, Charlottesville, VA, United States

2 - Moderator Panelist

Karen Hicklin, karen.hicklin@mountsinai.org, New York, NY, United States

We will gather experts in the area of health equity and operations research for a discussion regarding the current state of the field and emerging opportunities. The session will include an overview of the science of health equity research and social determinants of health, outline of funding and collaboration opportunities and, and perspectives on bringing an equity lens to all work we do within operations research and management science.

3 - Panelist

Julie Ivy, University of Michigan, Ann Arbor, MI, United States

4 - Panelist

Gian-Gabriel Garcia, Georgia Institute of Technology, Atlanta, GA, United States

5 - Panelist

Jovan Julien, Georgia Institute of Technology, Atlanta, GA, United States

6 - Panelist

Chaitra Gopalappa, University of Massachusetts, Amherst, Amherst, MA, United States

Advice for Early Career HAS Members

Panel Session

Health Applications Society

Co-Chair: Qiushi Chen, The Pennsylvania State University, University Park, PA, United States

1 - Moderator Panelist

Qiushi Chen, Pennsylvania State University, University Park, PA, United States

We propose a panel aimed at offering valuable insights to early career members of the Health Applications Society (HAS). In this panel, we plan to discuss several critical aspects of career development, including navigating funding opportunities beyond NSF, strategies for establishing a robust publication pipeline that balances Operations Research (OR) and interdisciplinary publications, student advising, and other challenges faced by early career researchers in the health modeling area.

2 - Panelist

Chaitra Gopalappa, University of Massachusetts, Amherst, Amherst, MA, United States

3 - Panelist

Oguzhan Alagoz, University of Wisconsin-Madison, Madison, WI, United States

4 - Panelist

David Hutton, University of Michigan, Ann Arbor, MI, United States

5 - Panelist

Pengyi Shi, Purdue University, West Lafayette, IN, United States

Causal Inference for Healthcare Applications

Invited Session

Health Applications Society

Chair: Gabriel Zayas-Caban, University of Wisconsin-Madison, Madison, WI, United States

1 - Quasi-Experimental Designs for Learning Health Systems

Gabriel Zayas-Caban, University of Wisconsin Madison, Madison, WI, United States

This project aims to improve the way healthcare systems evaluate the use of risk prediction models, which are tools used to identify patients who might benefit most from specific medical interventions. Traditionally, new interventions are tested through randomized controlled trials, but these trials can be challenging to run due to their complexity and high resource demands. We propose using an alternative approach known as regression discontinuity (RD) designs. The main challenge is to develop new RD designs that allow for updates to models and interventions as new information and clinical insights become available.

2 - Wild Regenerative Block Bootstrap for Harris Recurrent Markov Chains

Kyuseong Choi, Cornell Tech, New York, NY, United States

We consider Gaussian and bootstrap approximation for the supremum of additive functionals of aperiodic Harris recurrent Markov chains. The supremum is taken over a function class that may depend on the sample size, which allows for non-Donsker settings; that is, the empirical process need not have a weak limit in the space of bounded functions.

We first establish a non-asymptotic Gaussian approximation error, which holds at rates comparable to those for sums of high-dimensional independent or one-dependent vectors. Key to our derivation is the Nummelin splitting technique, which enables us to decompose the chain into either independent or one-dependent random blocks. Additionally, building upon the Nummelin splitting, we propose a Gaussian multiplier bootstrap for practical inference and establish its finite-sample guarantees in the strongly aperiodic case. Finally, we apply our bootstrap to construct a uniform confidence band for an invariant density within a certain class of diffusion processes.

3 - When Additive Noise Meets Unobserved Mediators: Bivariate Denoising Diffusion for Causal Discovery

Dominik Meier, Cornell Tech, New York City, NY, United States, Sujai Hiremath, Promit Ghosal, Kyra Gan

Distinguishing cause and effect from bivariate observational data is a foundational problem in many disciplines, but challenging without additional assumptions. Additive noise models (ANMs) are widely used to enable sample-efficient bivariate causal discovery.

However, conventional ANM-based methods fail when unobserved mediators corrupt the causal relationship between variables. This paper makes three key contributions: first, we rigorously characterize why standard ANM approaches

break down in the presence of unmeasured mediators. Second, we demonstrate that prior solutions for hidden mediation are brittle in finite sample settings, limiting their practical utility. To address these gaps, we propose Bivariate Denoising Diffusion (BiDD) for causal discovery, a method designed to handle latent noise introduced by unmeasured mediators. Unlike prior methods that infer directionality through mean squared error loss comparisons, our approach introduces a novel independence test statistic: during the noising and denoising processes for each variable, we condition on the other variable as input and evaluate the independence of the predicted noise relative to this input. We prove asymptotic consistency of BiDD under the ANM, and conjecture that it performs well under hidden mediation.

Experiments on synthetic and real-world data demonstrate consistent performance, outperforming existing methods in mediator-corrupted settings while maintaining strong performance in mediator-free settings.

4 - Two-Way Fixed Effects Models with Network Interference

Mayleen Cortez-Rodriguez, Cornell University, Ithaca, NY, United States, Haiyun He, Christina Yu, Matthew Eichhorn

Accurate and precise estimation of causal effects from panel data is important to decision-makers in many settings, including healthcare, online platforms, and policy-making. Two-way fixed effects (TWFE) models and linear regression are popular tools for estimating causal effects from panel data, as they can account for outcomes or treatment effects that change over time and vary across individuals. While often criticized for relying on strong, ultimately untestable parametric assumptions, these models are simple to understand, and the literature offers both theoretical and practical guarantees in many settings. Classic causal inference methods rely on the “no interference” assumption, which states that each individual’s outcome depends only on their own treatment and not on the treatment of others. This assumption is violated in many real-world scenarios, such as the effect of vaccination on disease reduction due to herd immunity. Although there is a growing body of literature on causal inference under interference for non-panel data, relatively few results exist for the panel data setting. To address this, we analytically and empirically explore TWFE-inspired models that incorporate network interference at varying levels of heterogeneity. We compare the performance of linear regression-based estimators under different interference models and discuss conditions for model selection based on computational experiments.

Generative AI for Decision-making

Invited Session

Decision Analysis Society

Chair: Guanting Chen, UNC Chapel Hill, Chapel Hill, NC, United States

1 - Risk Profiling and Modulation for LLMs

Yikai Wang, UNC Chapel Hill, Chapel Hill, NC, United States, Xiaocheng Li

Large language models (LLMs) are increasingly used for decision-making tasks under uncertainty; however, their risk profiles and how they are influenced by prompting and alignment methods remain underexplored. Existing studies have primarily examined personality prompting or multi-agent interactions, leaving open the question of how post-training influences the risk behavior of LLMs. In this work, we propose a new pipeline for eliciting, steering, and modulating LLMs' risk profiles, drawing on tools from behavioral economics and finance. Using utility-theoretic models, we compare pre-trained, instruction-tuned, and RLHF-aligned LLMs, and find that while instruction-tuned models exhibit behaviors consistent with some standard utility formulations, pre-trained and RLHF-aligned models deviate more from any utility models fitted. We further evaluate modulation strategies, including prompt engineering, in-context learning, and post-training, and show that post-training provides the most stable and effective modulation of risk preference. Our findings provide insights into the risk profiles of different classes and stages of LLMs and demonstrate how post-training modulates these profiles, laying the groundwork for future research on behavioral alignment and risk-aware LLM design.

2 - Why Agentic Design is Necessary for Data Analytics: The Limits of Multi-task Standalone LLM Inference

Daohong Tu, Stanford University, Stanford, CA, United States, Huaiyang Zhong, Guanting Chen

Agentic Large Language Models (LLMs) have gained attention for their ability to handle complex tasks through tool use, reasoning, and adaptive decision-making. However, the need for agentic design, beyond standard non-agentic approaches, has not been clearly established. In this work, we provide theoretical support for why agentic LLMs are necessary in data analytics. We demonstrate that, without agentic or reasoning-based mechanisms, using LLMs in standalone inference mode, even after pre-training and post-training enhancements such as supervised fine-tuning (SFT), or reinforcement learning from human feedback (RLHF), cannot reliably perform tasks in multi-task data science settings. Moreover, we theoretically and empirically show that mitigating this shortcoming would require modifications in the pre-training stage, which diverges from the standard LLM training paradigm. Our results characterize these limitations of standalone LLM inference and clarify where these approaches fall short in multi-task data science applications.

3 - Interactive LLM Agents for Data Science and Decision Analytics

Guanting Chen, UNC Chapel Hill, Chapel Hill, NC, United States, Yu Pan, Hanzhao Wang, Xiaocheng Li

We propose an interactive LLM agent framework designed specifically for data science and decision analytics. Unlike systems that focus primarily on automating computation, the agent emphasizes a professional yet interactive planning stage as its first step. Given a dataset, the agent collaborates with human users to interpret the data, clarify objectives, and determine an appropriate analysis or decision-making approach. This process reduces mistakes and hallucinations while ensuring that the chosen plan reflects domain-specific expertise contributed by practitioners, researchers, or instructors. Once consensus on the analysis plan is reached, the agent transitions from planning to execution by calling customizable local tool functions for computation and analysis. This design not only improves reliability by grounding results in trusted tools, but also makes the framework highly adaptable across different fields and problem domains. Through this combination of human expertise, structured planning, and tool integration, the framework provides a versatile pathway for incorporating LLM agents into professional workflows in data science, operations research, and decision analytics.

4 - Performative Risk Control for Reliable Decision-making by Generative AI

Zhun Deng, UNC at Chapel Hill, Chapel Hill, NC, United States, Victor Li, Qi Lei

Performativity of predictions refers to the phenomenon where prediction-informed decisions influence the very outcomes they aim to predict. This feedback loop is pervasive in both machine learning and decision-making. In this talk, we will introduce Performative Risk Control, a framework for calibrating predictive any blackbox models (e.g., LLMs) to achieve rigorous risk guarantees under performativity. We propose an iterative calibration process that ensures predictions are progressively improved while maintaining risk control, supported by theoretical guarantees. We also investigate the role of different risk measures and tail bounds in shaping the reliability of decision-making under performativity. Our study highlights new challenges and opportunities in decision-making theory with data feedback loop at the era of AI.

Advances in Empirical and Field Research on Healthcare Operations

Invited Session

Manufacturing and Service Operations Management (MSOM)

Chair: Zahra Mobini, Georgia Institute of Technology, Atlanta, United States

1 - Adverse Events Exposed: A Nationwide Study of Pediatric Emergency Departments

Mohamad Soltani, University of Alberta, Edmonton, AB, Canada, Mona Imanpoor Yourdshahy, Steven Shechter, Mahesh Nagarajan, Quynh Doan

In this presentation, we use data from pediatric emergency departments (EDs) across Canada to explore the impact of long ED waiting times on post-ED adverse events.

2 - Scaling up Timely Care: Combining Informational and Financial Interventions to Improve Follow-up Rates for High-Risk Urgent Care

Nazli Sonmez, ESMT GmbH, Berlin, Germany, Kamalini Ramdas, Manavi Sindal, Rengaraj Venkatesh, Priyanka Mahendrakar

Achieving impact at scale requires careful use of expensive resources. In this paper, we investigate the impact of combining a low-cost information intervention and a costly financial intervention to increase timely care access, in the context of emergency, high-consequence retina surgeries. In a two-stage randomized controlled trial of 2,100 emergency retina care patients conducted from 2019 to 2024 at Aravind Eye Hospital Pondicherry, all participants were first randomly assigned to view videos containing either emotional or technical content about the importance of timely follow-up. Next, financial incentives to follow-up were randomly provided among late patients. Notably, emotional videos increased on-time arrivals for the first appointment by 4.49%, demonstrating their potential for enhancing patient timely follow-up; technical videos had no significant effect on timely patient show-up rate. Moreover, financial incentives proved very effective for educated patients, increasing timely follow-up rates by 12–13%. However, these incentives had the opposite effect on less-educated patients, decreasing follow-up rates by 14–19%. This evidence sheds light on the importance of tailored interventions to improve the timely show-up rate of patients requiring high-consequence treatment to prevent needless blindness.

3 - Healthcare Algorithms and Disparities: Realized Value or Lost Opportunity?

Jiayi Liu, Virginia Tech, Blacksburg, VA, United States, Qi Wang, Ruba Aljafari, Anandhi Bharadwaj

The increasing adoption of artificial intelligence (AI) in healthcare holds promise for improving care quality, access, and patient outcomes. Yet concerns about algorithmic bias persist, particularly regarding its potential to exacerbate existing health disparities. This study examines the impact of healthcare algorithm adoption on racial disparities in clinical outcomes. Using six years of inpatient data analyzed through a difference-in-differences approach, we show that algorithm adoption improves outcomes for targeted groups, highlighting their potential for identifying and managing high-risk cases. However, these improvements are observed only among white patients, with no significant effects for non-white patients. Further analysis identifies substantial disparities in care delivery: non-white patients are much less likely to receive timely and intensive care following algorithm implementation—a key mechanism contributing to these disparities. These findings highlight the urgent need for greater scrutiny and reform in algorithm design and implementation to ensure equitable healthcare delivery.

4 - Beyond the Budget: the Unseen Costs of Maryland's Hospital Payment Reforms

Zahra Mobini, Georgia Institute of Technology, Atlanta, GA, United States, John McCandlish, Turgay Ayer

To rein in healthcare costs, Maryland implemented a global budget revenue (GBR) program for its hospitals, establishing yearly cost growth targets for all inpatient and outpatient services. Leveraging an extensive claims dataset for commercially insured individuals, our study empirically examines how the GBR influences care delivery patterns within hospitals.

5 - Pushing Past Patient Ratios: How a Recalculation of Workload Reshapes Nursing Imbalance and Alters Patient Care

Harshita Kajaria-Montag, Indiana University, Bloomington, IN, United States, RJ Niewoehner

Nurses play a pivotal role in patient care, but only if systems can hire enough of them and convince them to stay. Nurses make up the largest segment of the healthcare workforce, yet we find ourselves in the middle of a nursing crisis, and a shortage of nurses inevitably leads to overworked nurses. As a proxy for workload, most health systems carefully monitor the "nurse-to-patient ratio". We propose a fundamentally different tactic: using a painstakingly detailed workload tool, we observe how managers react to more accurate definitions of workload, including how they can better assign and balance work among their staff. We use archival data both before and after the launch of the workload tool from 67 unique nursing units operated by a large midwestern academic health system in the US. We observe over 4,000 nurses associated with over 60,000 patient encounters from January 2024 to March 2025. We find the introduction of the workload tool leads to load balancing, lower nurse attrition, and improved patient outcomes. Despite their virtues, most operations studies lack discussion of what actually happens when managers intervene and adjust server load. In contrast, we observe how managers deal with real-time fluctuations in load, enabling our study to push past generic suggestions of workflow towards actionable insights.

Wisdom of the Crowd

Invited Session

Decision Analysis Society

Chair: Long Zhao, NUS DAO, Singapore, Singapore

1 - Enhancing Forecast Aggregation with Side Information About Experts**Fuqing Li, National University of Singapore, Singapore, China, People's Republic of**

Traditional forecast aggregation methods, such as the linear opinion pool, rely primarily on limited historical forecast errors to assign aggregation weights. However, in many real-world settings, additional background information about the forecasters—such as their professional training or area of expertise—is also available. This paper explores how such background information can be systematically incorporated to enhance the accuracy of aggregated forecasts. Using about 50,000 time series from the M4 Forecasting Competition dataset, we demonstrate that our proposed method often outperforms standard benchmark approaches including equally weighted aggregation, especially when expert background characteristics are indicative of individual forecasting performance.

2 - Weighted Average Ensemble with Regularization**Xiaohe Zhang, George Washington University, Washington, DC, United States, Han Su, Xiaojia Guo**

Aggregating forecasts from multiple experts often yields more accurate results than relying on a single expert. Among ensemble methods, the weighted average is known for its effectiveness and intuitive nature. In this paper, we propose a regularized ensemble method that integrates both historical performance and current forecasts of the experts to optimize weight selection. Our method learns the optimal weights by minimizing the variance of the ensemble forecast while incorporating a regularization term informed by historical performance. With a few popular choices of regularization, our proposed procedure also has a natural connection with the Bayesian framework. The appealing practical utility of the proposed ensemble method is demonstrated by empirical studies of the M5 competition and the Survey of Professional Forecasters.

3 - How Many Products to Pool in Forecast Aggregation? Maybe as Many as Possible**Long Zhao, NUS DAO, Singapore, Singapore**

Combining multiple forecasts into a consensus often yields high accuracy, with simple averaging frequently outperforming complex weighting schemes—a phenomenon termed the "forecast combination puzzle." Recent work by Chen & Zhao (2025) proposes pooled inference, leveraging forecasts of related variables to improve weighting. This complex method excels in the M4 dataset, even with large covariance matrices and limited data. These contradictory findings challenge the conventional wisdom, raising key questions: Why and when does pooled inference succeed? This paper addresses this gap, providing a theoretical and empirical analysis of the conditions under which the more products are pooled, the better the aggregation performance.

4 - Harnessing Collective Wisdom: Crowd Judging in Enhancing Dispute Resolution on Two-Sided Platforms**Chong Zhang, Tilburg University, Tilburg, Netherlands, Zhonghong Kuang**

Emerging digital platforms are introducing innovative mechanisms for resolving disputes by leveraging crowd judging as an alternative to traditional adjudication systems. This study investigates the effectiveness of crowd judging in improving dispute resolution on two-sided platforms, particularly in scenarios involving meticulous reviews and fastidious customers. We develop a game-theoretic model in which sellers can either present evidence proving their innocence or introduce misleading information to sway judges. By comparing conventional platform-based adjudication with the crowd judging mechanism, we aim to determine if the latter offers superior market efficiency and increased sellers' profits. Additionally, we explore the impact of information sharing among judges on the efficiency of the crowd judging process, assessing its potential to enhance decision-making accuracy.

Chair: Xiu Yang, Lehigh University, Bethlehem, PA, 18015, United States

1 - Decentralized High-Dimensional Inference over Mesh Networks: a Unified Perspective**Marie Maros, Texas A&M University, College Station, TX, United States**

We consider the problem of solving high-dimensional statistical inference problems over a network of agents (with no coordinating agent) who have exclusive access to a fraction of the total available samples. In the high-dimensional setting, the problem dimension is much larger than the total number of available samples, making the problem ill-conditioned. Despite this, we empirically observe that obtaining a statistically meaning solution is possible with many existing decentralized schemes, given that underlying parameter to estimate lies in a low dimensional subspace. Our observations challenge the existing theories in two key ways: (i) most decentralized schemes do not break down as the problem dimensionality increases, and (ii) decentralized schemes that are expected to behave like one another behave very differently in high dimensions. To understand the behavior of decentralized optimization methods in high-dimensional inference we introduce a unified framework and analysis, allowing us to develop an understanding of the mechanisms enabling dimension independent performance of decentralized schemes.

2 - Quantum Circuit-Based Stochastic Optimization Integrated with a Quantum Probability Distribution Generator**Taihei Kuroiwa, The University of Electro-Communications, Chofu, Japan, Daiki Yamazaki, Yuya Ito, Kiria Yamashita, Daiki Sasaki, Ryosuke Koga, Keita Takahashi, Kodai Shiba, Tomah Sogabe**

Stochastic optimization is widely employed in domains such as energy system operation, supply-chain management, and financial portfolio optimization to account for uncertainty. However, as the number of scenarios grows, traditional scenario-based models and sample average approximation suffer from exponential increases in computational time and memory, limiting their applicability to large-scale problems.

In this work, we propose a quantum circuit-based stochastic optimization algorithm that integrates a pre-trained conditional quantum generative adversarial network (c-qGAN) directly into the quantum approximate optimization algorithm (QAOA). First, the conditional qGAN is trained offline to encode 2^n discrete scenarios into an n -qubit probability distribution generator. Next, the trained generator circuit is entangled with the QAOA circuit via controlled gates, enabling optimization decisions to incorporate uncertainty within the quantum circuit.

We apply our method to a renewable-integrated stochastic unit commitment problem, demonstrating that circuit depth and gate count scale polynomially with $\log_2$ (scenario count). Furthermore, on Qiskit simulators, our approach achieves solution quality on par with classical scenario-based optimization. Our results suggest that quantum circuit-based stochastic optimization could offer a viable, scalable alternative to classical methods as quantum hardware matures.

3 - Solving Constrained Marginally Convex Optimization Problems**Samuel Kwan, University of Chicago, Chicago, IL, United States, Siva Ramani, Andrew Schaefer**

In this paper, we attempt to solve constrained marginally convex optimization problems. We introduce an algorithm known as the upper bound coordinate descent. We show that this algorithm converges to a stationary point. We then apply this algorithm to solve an inverse Markov Decision Process problem, which is bilinear, hence marginally convex, by nature.

4 - Robust Admission via Two-Stage Stable Matching Under Ranking Uncertainty

Gustavo Angulo, Pontificia Universidad Católica de Chile, Santiago, Chile, Matías Giddings, Pablo Marshall

The Bachillerato Inicia UC program offers a pathway for students from Chilean technical high schools to articulate into undergraduate programs at Pontificia Universidad Católica de Chile. Upon applying, candidates rank up to three preferred programs. However, articulation is determined only after one year, based on their academic ranking within the cohort - a value unknown at the time of admission.

This setting gives rise to a two-stage admission problem with downstream matching constraints and exogenous uncertainty. The challenge is to select a feasible subset of students to admit, respecting the order of applicant scores, while guaranteeing that, under any realization of final rankings, each admitted student can be matched to one of their declared preferences, respecting program capacities.

We formalize this as a two-stage stable matching problem under ranking uncertainty and design an algorithm that characterizes the set of robustly admissible candidates. The model ensures articulation guarantees that are consistent with declared preferences and capacity constraints. We present implementation results from the 2024 and 2025 admission cycles. Joint work with Matías Giddings and Pablo Marshall.

5 - A Procedure to Assess Nonconvexity via Shortest Feasible Paths

Cameron Khanpour, Georgia Institute of Technology, Atlanta, GA, United States, Daniel Turizo, Samuel Talkington, Daniel Molzahn

We present a procedure that, given a compact non-convex set S , provides a metric representing how "close" S is to being a convex set. This metric is defined as the ratio of the *shortest feasible path* contained entirely within S to the Euclidean distance between the *endpoints* of such a path. Points from the set S are sampled uniformly through an efficient mixing algorithm for general QCQPs. By computing these ratios over all sampled pairs of points, we obtain an empirical distribution whose average provides a quantitative measure of the degree of convexity of S . We prove convergence of this sampling-based estimate to a true measure of convexity under mild assumptions. As an illustrative application, we assess the non-convex feasible sets of the optimal power flow (OPF) problem used to determine generator setpoints in electric power grids, independent of any specific objective function. We demonstrate the effectiveness of our procedure with numerical experiments using MATPOWER test cases.

6 - Resilient Consensus Without Finite TIME Detection Guarantees

Sarper Aydin, Harvard University, Cambridge, MA, United States, Orhan Eren Akgun, Stephanie Gil, Angelia Nedich

This paper investigates the asymptotic convergence of consensus processes under random malicious attacks with generalized time-varying attack probabilities. Agents leverage trust observations to identify their legitimate neighbors, but these generalized attack probabilities do not render any finite-time detection guarantees. In the absence of a finite-time detection, we demonstrate convergence of the consensus process in probability and expectation using misclassification probability bounds. We show that the weight matrices converge to the ideal weight matrix (which would have been used in the absence of malicious agents) in probability, and the consensus dynamics for legitimate agents reaches an agreement in probability and expectation. Numerical simulations validate our theoretical findings for several attack probability sequences.

7 - Distributionally Robust Optimization for Distribution Network Design Problem with Circular Transportation

Mianxing Zhong, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Defeng Sun, Lixin Tang

Distribution network design Problem, which involves facility location, warehousing, transportation decisions, is of fundamental importance for companies to be competitive on the market. In this paper, we study a three-level logistic distribution network problem with circular transportation and direct shipment under the uncertainty of discount factor on transportation. To describe the uncertainty, we introduce a Wasserstein distance-based ambiguity set and establish a two-stage distributionally robust optimization model which is converted into a certain mixed integer linear programming model. We propose a Benders decomposition approach to solve the problem which is enhanced through valid inequalities, combinatorial Benders' cuts and high density Pareto cuts. Computational experiments demonstrate that the performance of two-stage distributionally robust optimization model solutions can hedge against the uncertainty in discount factor on transportation flexibly. Finally, this paper shows the effectiveness and robustness of the model and provides managerial insights for distribution network design and management.

8 - Noise-Aware Optimization for Variational Quantum Algorithms

Xiu Yang, Lehigh University, Bethlehem, PA, United States

The success of variational quantum algorithms (VQAs) relies on classical optimization algorithms that allow function information distorted by sampling and hardware noise. We introduce a noise-aware optimization scheme that estimates gradient and curvature information from finite-difference samples then optimizes the objective using a quasi-Newton algorithm framework. Applied to the Quantum Approximate Optimization Algorithm (QAOA) for Max-Cut, the method aims to cut circuit-evaluation costs and maintain steady progress with noise. Preliminary numerical results demonstrate the superior performance compared to standard gradient-free approaches.

Special Issue of Decision Analysis on AI

Invited Session

Decision Analysis Society

Chair: Ali Abbas, University of Southern California, Los Angeles, CA, United States

1 - Chatgpt vs. Experts: Can Genai Develop High-Quality Organizational and Policy Objectives?

Jay Simon, American University, Washington, DC, United States, Johannes Siebert

We explore the efficacy of GenAI for value-focused thinking, specifically the ability to generate high-quality sets of objectives for organizational or policy decisions. Overall, we find that most of the GenAI objectives are viable individually, but the sets as a whole are highly flawed in the given decision setting. They often include non-essential considerations while omitting important ones. In addition, they are redundant and non-decomposable, often because of a tendency to include means objectives even when explicitly instructed not to. Prompt improvements mitigate the problems only slightly. The results provide further evidence of the importance of a human in the loop; in this case, GenAI tools are helpful for brainstorming objectives, but an expert is needed before the results are used to support decision making. To facilitate this, a four-step approach incorporating the relative strengths of both GenAI and decision analysts is presented and demonstrated.

2 - Comparing Humans and LLMs Alternative, Preferences , and Uncertainties for Decisions

Ali Abbas, University of Southern California, Los Angeles, CA, United States, Barbara Mellers, Rachel Monger

This talk presents the results of two experiments that compare the relevance and redundancy of inputs to decision quality from individuals and Chat GPT. The experiments were conducted using the social media platform Ahoona. Individuals were asked to provide inputs to decision quality without seeing the GPT inputs. A second experiment compared the individual inputs to those of Chat GPT with regeneration and probing. The work also explores the impact of exposure to decision education on this comparison.

3 - Toward Synthesizing AI and Decision Analysis: Initial Thoughts

Jeffrey Keisler, University of Massachusetts-Boston, Boston, MA, United States

We consider qualitatively which DA and adjacent tasks are performed well by AI, by humans, or both—and how important these tasks are to the decision process. This lens suggests directions for synthesizing AI and DA into something more than the sum of their parts. In this, AI's greatest value may lie not in formal modeling, but in helping connect those models to reality.

4 - AI as Opportunity for Decision Education

Chris Spetzler, Decision Education Foundation, Portola Valley, CA, United States

AI holds great promise in augmenting human intelligence, specifically in the learning and teaching of decision skills. This presentation will share initial experiences using AI in decision education. Decision Education Foundation's (DEF) work with high school students at The Socratic Experience (TSE) online high school and at the Decision Quality Center at the Illinois Institute of Technology are two current examples with additional applications in store. At TSE, Eric Horvitz's Decision Insights VIII helped students evaluate potential ways to approach a gap year, while reinforcing prior learning on a highly relevant and relatively complicated application of decision analysis to students' lives. At Illinois Tech, an AI decision tool is being developed to allow students to coach an student/bot facing a challenging decision. This promising tool helps students to both see and demonstrate the value of their decision skills in an active way with immediate feedback. The DQ Center, in partnership with DEF, is working to ensure all Illinois Tech students learn principles of Decision Quality as a part of their undergraduate experience. The AI tool holds the promise of ensuring high and consistent standards across instructors for teaching, learning and assessment of Decision Quality.

Practice Driven Research in Supply Chain

Invited Session

MSOM: Supply Chain

Chair: Liang (Leon) Xu, Singapore Management University, Singapore, Singapore

1 - Suppliers' Self-Disclosed Vulnerability and Brand Perception in Sustainable Supply Chain Practices

Amolwan Jittamai, University of Houston, Houston, TX, United States, Ravi Aron

This research examines how voluntary self-disclosure of negative information by a brand about its supply chain practices affects consumer perceptions of the brand. Using a mixed experimental design combining between-subjects (brand positioning and level of self-disclosed negative information) and within-subjects (whether the brand self-disclosed negative information) factors, we investigate how transparency through self-disclosure of negative information regarding the brand's sustainable supply chain practices influences consumers' level of trust, perceived product quality, purchase intention, and willingness to pay. In addition, we investigate whether a brand can game the market by strategically under-investing in sustainable practices and disclosing its deficits to benefit from consumers' trust.

We find that when comparing two brands that have implemented the same levels of sustainable practices, the brand that fully self-revealed its deficits is rewarded by consumers. Both trust and perceived product quality generated through self-disclosed negative information led to positive consumer outcomes regardless of brand positioning. In addition, we find that a brand cannot act strategically by under-investing in sustainable practices as consumers penalize suppliers with lower trust for under investment in sustainable practices even if the deficits are self-revealed. This research extends transparency studies by demonstrating that self-revealed vulnerability by disclosing negative information can build consumer trust and enhance perceived product quality. However, a brand cannot behave in an opportunistic and strategic manner and attempt to free ride on the economic goodwill generated by the self-revelation of deficits and under invest in sustainable practices.

2 - AI-Driven Bidding in Procurement Auctions

Jingyi Tian, University of Houston, Houston, TX, United States, Meng Li

As online auction platforms advance, bidders increasingly turn to artificial intelligence (AI) for strategic advantages. This paper studies AI-driven bidding behavior in second-price procurement auctions through conducting experiments with agents trained by a model-free, value-based reinforcement learning algorithm: the Deep Q-Network (DQN). Through extensive simulations under varying competition levels and randomized initializations, we identify a robust tendency toward overbidding as the algorithm converges to a stable state. Bids exceed costs consistently, and the gap widens as competition intensifies. This behavior departs from the incentive-compatible Nash equilibrium, resulting in inflated procurement costs. By connecting DQN's iterative value-based updating mechanism to the reward structure in repeated auction games, we show that this systematic overbidding arises due to the internalization of positive externalities created by elevated bids, which enhance competitors' expected rewards. This interdependent dynamic destabilizes truthful bidding, fostering implicit collusive behavior despite the absence of explicit coordination. To mitigate these collusive outcomes, we propose and experimentally evaluate two targeted strategies: limiting the number of bidders and imposing lower reserve-price ceilings. Supplemental experiments involving enriched informational inputs to the algorithm further reveal the nuanced ways in which the information environment influences the learning process. Our findings uncover a novel, unintended form of algorithmic collusion in procurement auctions, highlight critical gaps in existing antitrust policies, and provide practical design and regulatory insights to help auction designers embrace AI-driven bidding without compromising market competitiveness and efficiency.

3 - Automated Decision Framework for Multi-Paradigm Warehouse Slotting Optimization

Aakash Bhatt, Chewy, Inc., San Jose, CA, United States

Modern e-commerce fulfillment operations face growing complexity in storage location assignment across multi-paradigm facilities where automated robotic systems and manual pick modules coexist. Traditional approaches either focus on single storage paradigms or apply isolated heuristics to each system, leading to locally optimized decisions that undermine global fulfillment efficiency.

We present a novel two-stage mixed integer programming framework that fully automates warehouse slotting decisions across all storage paradigms. Its core innovation is a hierarchical decomposition approach that handles a 70K+ SKU catalog across 100K+ locations while maintaining computational traceability. The first-stage MIP incorporates cross-paradigm constraints—pick cost, machine capacity, and replenishment efficiency—to optimize macro-allocation between robotic and manual storage modules. The second-stage MIP then solves location-specific assignments with affinity-based travel minimization, achieving global optimality beyond the reach of traditional sequential methods. The resulting move instructions are automatically transmitted to the warehouse management system, enabling iterative convergence toward optimal item placement.

Thorough simulation testing and successful implementation at a Chewy fulfillment center (processing 100K+ daily orders) demonstrate improvements over both manual expert slotting and single-paradigm optimization: 15% increase in pick rates and 20% reduction in cycle times compared to previous best-practice configurations. The system re-optimizes weekly with adaptive implementation pacing (3-5% of inventory relocated per cycle) to balance disruption costs against performance gains. This autonomous approach represents an advancement in warehouse optimization by bridging theoretical models with implementation practicality in complex multi-paradigm environments.

1 - Routing with Delayed Revelation of Feature Information

Xiaoquan Gao, Singapore Management University, Singapore, Singapore, Pengyi Shi

We study the routing problem for heterogeneous customer arrivals, where individual features are initially unavailable and only revealed after evaluation. This delay can lead to inefficiencies in resource allocation, particularly in systems with diverse user classes requiring personalized assessments. To address this challenge, we propose a two-stage approach. In the first stage, individuals are allocated to different programs based on arrival counts, historical class data, and facility occupancy, enabling proactive resource planning. In the second stage, individualized placement decisions are made after evaluations. We establish a performance bound relative to a full-information Markov Decision Process (MDP), provided that second-stage routing follows treatment effect rankings. Computationally, we develop a fluid model and apply constrained linear quadratic regulation (LQR) to derive an asymptotically optimal, easy-to-implement linear decision rule for the first stage. Simulations calibrated with real-world data from community corrections demonstrate that our approach outperforms existing threshold-based policies, improving staffing and resource coordination without requiring immediate judicial decisions for each individual.

2 - Causal Reinforcement Learning and Centaurs: Making AI Impactful in Healthcare

Soroush Saghaian, Harvard University, Cambridge, MA, United States

There is increasing evidence that Machine Learning and Artificial intelligence algorithms can be used to enhance clinical care. In this talk, I address two critical aspects that can significantly improve the impact of such algorithms in healthcare practices: (1) moving beyond associations and creating algorithms capable of causal reasoning under ambiguity, and (2) a human-algorithm “centaur” model of care and decision-making, in which the power of human intuition is combined with the outstanding capabilities of algorithms. I describe our latest research on these subjects at the Public Impact Analytics Science Lab (PIAS-Lab) at Harvard, and discuss findings based on our various collaborations with the Mayo Clinic, Mass General Hospital, and some other public and private organizations.

3 - Holistic Optimization of Operating Rooms

Kimberly Villalobos Carballo, New York University, New York, MA, United States

Surgeries are a key component of hospitals’ revenue and a vital element of patient care. We propose a holistic framework for operating room (OR) optimization using robust and discrete optimization techniques. Our three-stage approach includes (1) demand forecasting, (2) tactical definition and allocation of OR blocks to surgeons, and (3) operational-level online surgery scheduling. Simulations demonstrate that our method can reduce inpatient census by 6–10% and increase OR utilization by 32%, highlighting its potential to enhance both care delivery and hospital efficiency.

4 - Exact Sensitivity Analysis of Markov Reward Processes via Algebraic Geometry: Application to Cost-Effectiveness

Timothy Chan, University of Toronto, Toronto, ON, Canada, Muhammad Maaz

We introduce a new approach for deterministic sensitivity analysis of Markov reward processes, commonly used in cost-effectiveness analyses, via reformulation into a polynomial system. Our approach leverages cylindrical algebraic decomposition (CAD), a technique arising from algebraic geometry that provides an exact description of all solutions to a polynomial system. While it is typically intractable to build a CAD for systems with more than a few variables, we show that a special class of polynomial systems, which includes the polynomials arising from Markov reward processes, can be analyzed much more tractably. We establish several theoretical results about such systems and develop a specialized algorithm to construct their CAD, which allows us to perform exact, multi-way sensitivity analysis for common health economic analyses. Finally, we apply it to two case studies, one with synthetic data and one that re-analyzes a previous cost-effectiveness analysis from the literature, demonstrating advantages of our approach over standard techniques. We develop an open-source software package that implements our algorithm. Our software and code are available at: <https://github.com/mmaaz-git/markovag>.

5 - Measuring the Heterogeneous Effect of Emergency Department Boarding on Inpatient Length of Stay: Toward Efficient and Equitable Inpatient Bed Assignment

Xiaole (Alyssa) Liu, New York University Stern School of Business, New York, NY, United States, Jing Dong, Martin Copenhaver, Yosef Berlyand

Emergency Department (ED) boarding, the practice of holding admitted patients in the ED while awaiting an inpatient bed, is a common challenge in hospitals worldwide. It is a major contributor to ED crowding and raises concerns about the quality of care. When inpatient bed capacity is limited, hospitals must decide how to prioritize boarding patients for admission in a way that is both efficient and equitable. In this study, we investigate the heterogeneous causal impact of ED boarding on inpatient length of stay (LOS), a key metric influencing downstream capacity. Using methods from double machine learning, instrumental variables, and heterogeneous treatment effect modeling, we identify patient subgroups for whom prolonged boarding has different effects on LOS. We then integrate these individualized effect estimates with queueing models and policy learning techniques to design inpatient bed assignment policies that reduce overall ED boarding time. A key feature of our approach is the explicit integration of fairness considerations into operational policy design. First, we construct policies that enforce group fairness. Second, we propose a class of policies that navigates the tradeoff between system efficiency and individual fairness. We validate our proposed policies using a high-fidelity, trace-driven simulation model calibrated with real hospital data. Results show that our policies can substantially reduce the average ED boarding times by over 75% compared to the current bed assignment policy, while maintaining strong fairness performance.

1 - Large Language Models for Market Research: a Data-Augmentation Approach

Mengxin Selene Wang, The University of Texas at Dallas, Richardson, TX, United States, Dennis Zhang, Heng Zhang

Large Language Models (LLMs) have transformed artificial intelligence by excelling in complex natural language processing tasks. Their ability to generate human-like text has opened new possibilities for market research, particularly in conjoint analysis, where understanding consumer preferences is essential but often resource-intensive. Traditional survey-based methods face limitations in scalability and cost, making LLM-generated data a promising alternative. However, while LLMs have the potential to simulate real consumer behavior, recent studies highlight a significant gap between LLM-generated and human data, with biases introduced when substituting between the two. In this paper, we address this gap by proposing a novel data augmentation approach that efficiently integrates LLM-generated data with real data in conjoint analysis. Our method leverages transfer learning principles to debias the LLM-generated data using a small amount of human data. This results in statistically robust estimators with consistent and asymptotically normal properties, in contrast to naive approaches that simply substitute human data with LLM-generated data, which can exacerbate bias. We validate our framework through an empirical study on COVID-19 vaccine preferences, demonstrating its superior ability to reduce estimation error and save data and costs by 24.9% to 79.8%. In contrast, naive approaches fail to save data due to the inherent biases in LLM-generated data compared to human data. Another empirical study on sports car choices validates the robustness of our results. Our findings suggest that while LLM-generated data is not a direct substitute for human responses, it can serve as a valuable complement when used within a robust statistical framework.

2 - Auto-Formulating Dynamic Programming Problems with Large Language Models

Jingyuan Yang, University of Chicago, Booth School of Business, Chicago, IL, United States

Dynamic programming (DP) is a fundamental method in operations research, but formulating DP models has traditionally required expert knowledge of both the problem context and DP techniques. Large Language Models (LLMs) offer the potential to automate this process. However, DP problems pose unique challenges due to their inherently stochastic transitions and the limited availability of training data. These factors make it difficult to directly apply existing LLM-based models or frameworks developed for other optimization problems, such as linear or integer programming.

We introduce DP-Bench, the first benchmark covering a wide range of textbook-level DP problems to enable systematic evaluation. We present Dynamic Programming Language Model (DPLM), a 7B-parameter specialized model that achieves performance comparable to state-of-the-art LLMs like OpenAI's o1 and DeepSeek-R1, and surpasses them on hard problems. Central to DPLM's effectiveness is DualReflect, our novel synthetic data generation pipeline, designed to scale up training data from a limited set of initial examples. DualReflect combines forward generation for diversity and backward generation for reliability. Our results reveal a key insight: backward generation is favored in low-data regimes for its strong correctness guarantees, while forward generation, though lacking such guarantees, becomes increasingly valuable at scale for introducing diverse formulations. This trade-off highlights the complementary strengths of both approaches and the importance of combining them.

3 - From Qualification Exams to Practice: Testing LLMs on Solving Stochastic Modeling Problems

Tianyi Peng, Columbia University, New York, NY, United States, Akshit Kumar, Yuhang Wu, Assaf Zeevi

Large language models (LLMs) have exhibited capabilities comparable to those of human experts in various fields. However, their modeling abilities---the process of converting real-life problems (or their verbal descriptions) into sensible mathematical models---have been underexplored. In this work, we take the first step to evaluate LLMs' abilities to solve stochastic-modeling problems, a model class at the core of Operations Research (OR) and decision-making more broadly. We manually procure a representative set of graduate-level homework and doctoral qualification-exam problems and test LLMs' abilities to solve them. We further leverage SimOpt, an open-source library of simulation-optimization problems and solvers, to investigate LLMs' abilities to make real-world decisions. Our results show that, though state-of-the-art LLMs demonstrate proficiency on par with human experts in both classroom and practical settings, a nontrivial amount of work is still needed to reliably automate the stochastic-modeling pipeline in reality.

4 - Synthetic but Not Infinite: How Much LLM-Generated Data to use in Market Research

Linwei Xin, Cornell University, Ithaca, NY, United States, Qichuan Yin

Large Language Models (LLMs) have transformed data generation by enabling scalable synthetic data augmentation. This paper explores the optimal use of LLM-generated synthetic data in market research, with a focus on improving choice model estimation under limited training data. We introduce a framework, supported by a theoretical analysis, that identifies the optimal ratio of synthetic to real data and characterizes the resulting estimation error of this hybrid approach.

Chair: Zuguang Gao, University of California, Irvine, Irvine, CA, 92697, United States

1 - From Wheels to Wallet: Optimizing Transit Service, Pricing, and Funding Allocation

Jingwei Zhang, Cornell University, Ithaca, NY, United States, Owen Wu

Public transit systems in many U.S. cities face a dual crisis of declining ridership and financial instability, exacerbated by income segregation that creates diverse, often unmet, rider needs. This paper addresses the critical challenge of how transit agencies can optimize pricing, service levels (time-related factors), and the internal allocation of limited budgets across income-segregated regions to maximize total ridership. We develop a game-theoretic, bilevel optimization model where a budget-constrained transit agency sets differentiated or uniform fares and service times, anticipating the mode choices of utility-maximizing consumers from distinct high- and low-income regions.

Our analysis reveals that under a differentiated policy, the optimal allocation of the total budget between income regions is non-monotonic, depending critically on income disparity, service improvement costs, and overall budget availability. For instance, substantial budgets may favor high-income regions if service improvements are inexpensive and disparity is high, but under fiscal scarcity, low-income regions might receive more to prevent ridership collapse. We also demonstrate the potential for bidirectional cross-subsidization, challenging common assumptions. Comparing differentiated policies with uniform benchmarks, we identify conditions where differentiation not only improves total ridership but can also yield targeted benefits for specific income groups. These findings offer actionable insights for transit agencies, suggesting that strategically differentiating pricing, service, and particularly budget allocation based on income-related sensitivities can more effectively achieve ridership goals than traditional uniform policies, providing a novel operations management approach to a pressing public service challenge.

2 - Climate Change and Thermostat Behavior: Empirical Evidence, the Impact, and Interventions

Michael Blair, Wilfrid Laurier University, Waterloo, ON, Canada, Saed Alizamir, Shouqiang Wang

Using a rich micro-level dataset, we empirically analyze smart thermostat data to understand the relationship between households' thermostat settings and their ambient environment. Within this data we observe two key decision levers that households use to manage their home heating and cooling. Combining a variety of methodological tools including Dynamic Linear Models, random effects, and Bayesian Statistics, we develop models for these behavior levers and study how households are impacted by varying weather conditions. A critical insight from these models is that households typically react to the weather in a comfort-seeking manner, leading to increased energy usage. We also find that this behavior is more prevalent in households that routinely override the settings they have pre-programmed into the thermostat. With these insights in mind, we leverage well-established models to create realistic estimates of future weather conditions under a variety of climate change scenarios and combine these scenarios with our statistical models to estimate the impact of climate change on how households use their thermostats. Specifically, we predict future household behavior and investigate the resulting changes in energy usage for heating and cooling. These changes have a profound impact on the operations of the energy grid specifically relating to operating costs, grid capacity, and reliance on intermittent renewable energy sources. The insights derived from our research provide a valuable framework to evaluate and design interventions. Furthermore, we discuss two changes that smart thermostats manufacturers could make to potentially alleviate the behavioral challenges identified.

3 - Multi-Period Aggregation of Distributed Energy Resources

Lisa Hillas, University of Auckland, Auckland, New Zealand, Zuguang Gao

This paper looks at the problem of how distributed energy resources (DERs), such as household-level solar panels, should be integrated into the wholesale electricity market. We assume that DER owners have access to batteries that allow them to transfer power across time periods. We look at how DER owners should choose to consume, exchange with the market, and buy or sell power. Additionally, given the choices of the DER owners, we look at how an aggregator whose role is to procure electricity from DERs and sell the electricity in the wholesale market should set prices to the DER owners.

1 - Bias in Offline Retailing Experiment: Evidence and Solution

Jiayi Zhang, Washington University in St. Louis, St Louis, MO, United States, Zhiqi Zhang, Dennis Zhang, Ruohan Zhan

Product-based randomization, where a random subset of products receives treatment while others serve as controls, is commonly used in offline retailing experiments. We show this can result in biased causal inference due to consumer substitution and complementarity behaviors. We propose a double-machine-learning-based debiasing method with theoretical guarantees and empirical performance.

2 - Can Personalized Pricing be Progressive?

Titing Cui, University of Tulsa, Tulsa, OK, United States, Max Biggs, Michael Hamilton, Enfeng Xing

Traditional welfare analysis evaluates pricing policies based on aggregate revenue and customer surplus. However, modern approaches increasingly emphasize equity by asking not just how much aggregate utility is derived, but by whom. In this work, we examine market outcomes under a new notion of *proportional surplus*, which measures the percentage of a customer's valuation that is retained as surplus. Proportional surplus provides a more equitable lens by which to view market outcomes, assigning greater weight to utility gained by customers with the least ability to pay. Further, we demonstrate that although traditional customer surplus often decreases when firms price discriminate, proportional surplus increases under moderate levels of revenue-maximizing price discrimination in many natural markets. These findings challenge the conventional belief that price discrimination harms customers, and suggests instead that modest amounts of price discrimination can improve outcomes for both firms and the markets that they serve.

3 - Learning to Optimize Service Upgrades in Systems with Reusable Resources

Xuchen Liu, University of California, Berkeley, Berkeley, CA, United States, Huiwen Jia

We study a revenue management problem in a service system with reusable resources over a finite horizon T . Customers arrive according to a Poisson process and have exponentially distributed service durations, both with unknown parameters. The system operates under a fixed base price, while also offering an implicit upgrade option that allows customers to extend their service duration by a prespecified factor at a fixed discounted unit price. Customers choose between the base and upgraded options according to an unknown preference model. The objective is to learn the optimal upgrade option from a discrete set of candidates to maximize cumulative revenue. We propose a Batch Upper Confidence Bound (BUCB) algorithm that jointly (i) learns the system dynamics, i.e., the arrival rate, service rate, and upgrade choice probability for each option, and (ii) maximizes revenue under incomplete information. We establish high-probability bounds on parameter estimation, which serves as the basis of theoretical performance guarantees BUCB. Numerical experiments highlight the algorithm's efficiency and demonstrate substantial revenue improvements over single-price benchmarks.

4 - Familiarity-Based Dynamic Pricing with Hierarchical Bayes Estimation of Customer Choices

Binghan Kou, University of Wisconsin, Superior, Superior, WI, United States, Hongmin Li, Yuqi Yang

Repeated consumption affects customers' familiarity with a product and influences their preference for future consumption of the product. This effect varies by individual. For some customers, more familiarity increases their appetite for consumption; for others, the opposite may hold true. More generally, individuals' preferences may be nonmonotonic with respect to familiarity and exhibit various patterns. Accounting for familiarity-based preference creates opportunities for the firm to tailor pricing decisions to each customer's specific preference pattern. A major hurdle, however, is the complexity of deciphering the diverse familiarity-based preference patterns embedded in transaction data and integrating this information into the pricing decision. In this paper, we present a value-passing dynamic pricing strategy that is optimal under a familiarity-based logit choice model. In this context, we develop a versatile finite-state pricing model as an integrated solution that enables not only analytical tractability but also empirical estimation of the familiarity effect. Employing a hierarchical Bayes estimation approach, we demonstrate how this data-driven dynamic pricing strategy improves a firm's bottom line.

5 - Balancing Profitability and Food Waste in Online Grocery: a General Fluid Analysis of Inventory-Adaptive Ranking

Alys Liang, McGill, Montreal, QC, Canada, Huanan Zhang, Sajjad Najafi

Food waste and revenue loss are critical challenges for online grocery retailers, undermining profitability and driving up operational costs. At the retail level, waste is often driven by excess inventory and product expiration. This paper explores how dynamic product ranking can be leveraged to reduce waste by accounting for volatile inventory levels and quality degradation, especially in settings where pricing flexibility and replenishment agility are limited. We demonstrate that adaptive ranking policies can play a vital role in balancing sales performance with sustainability goals.

1 - Multi-Group Mean Estimation via Active Learning

Adam Elmachtoub, Columbia University, NYC, NY, United States, Abdellah Aznag, Rachel Cummings

We study a fundamental learning problem over multiple groups with unknown data distributions, where an analyst would like to learn the mean of each group. Moreover, we want to ensure that this data is collected in a relatively fair manner such that the noise of the estimate of each group is reasonable. In particular, we focus on settings where data are collected dynamically, which is important in adaptive experimentation for online platforms or adaptive clinical trials for healthcare. In our model, we employ an active learning framework to sequentially collect samples with bandit feedback, observing a sample in each period from the chosen group. After observing a sample, the analyst updates their estimate of the mean and variance of that group and chooses the next group accordingly. The analyst's objective is to dynamically collect samples to minimize the collective noise of the estimators, measured by the norm of the vector of variances of the mean estimators.

We propose an algorithm, Variance-UCB, that sequentially selects groups according to an upper confidence bound on the variance estimate. We provide a general theoretical framework for providing efficient bounds on learning from any underlying distribution where the variances can be estimated reasonably. This framework yields upper bounds on regret that improve significantly upon all existing bounds, as well as a collection of new results for different objectives and distributions than those previously studied.

2 - Design-Based Confidence Sequences: Stopping Experiments Earlier with Netflix

Dae Woong Ham, University of Michigan - Ross Business School, Ann Arbor, MI, United States, Iavor Bojinov, Michael Lindon, Martin Tingley

Randomized experiments have become the standard method for companies to evaluate the performance of new products or services. In addition to augmenting managers' decision-making, experimentation mitigates risk by limiting the proportion of customers exposed to innovation. Since many experiments are on customers arriving sequentially, a potential solution is to allow managers to "peek" at the results when new data becomes available and stop the test if the results are statistically significant. Unfortunately, peeking invalidates the statistical guarantees for standard statistical analysis and leads to uncontrolled type-1 error. Our paper provides valid design-based confidence sequences, sequences of confidence intervals with uniform type-1 error guarantees over time for various sequential experiments in an assumption-light manner. In particular, we focus on finite-sample estimands defined on the study participants as a direct measure of the incurred risks by companies. Our proposed confidence sequences are valid for a large class of experiments, including multi-arm bandits, time series, and panel experiments. We further provide a variance reduction technique incorporating modeling assumptions and covariates. Finally, we demonstrate the effectiveness of our proposed approach through a simulation study and three real-world

applications from Netflix. Our results show that by using our confidence sequence, harmful experiments could be stopped after only observing a handful of units; for instance, an experiment that Netflix ran on its sign-up page on 30,000 potential customers would have been stopped by our method on the first day before 100 observations.

3 - Optimal Offline Policy Learning for Mnl Bandits

Yuxuan Han, New York University, New York, NY, United States, Han Zhong, Miao Lu, Jose Blanchet, Zhengyuan Zhou

Policy learning of the Multinomial Logit (MNL) bandits is a widely studied problem in data-driven assortment optimization, where sellers need to determine the optimal subset of the products to offer based on historical customer choice data. Most existing research on MNL bandits focuses on the online policy learning via repeated interaction with customers, such exploration can be costly in many real-world scenarios. In this talk, we explore the offline learning paradigm by providing a complete characterization of the complexity of offline MNL bandit learning problems. We show that the "optimal item coverage"—where each item in the optimal assortment appears sufficiently often in historical data—is necessary for efficient offline learning by establishing the corresponding information-theoretic lower bounds. For sufficiency, we show that the performance of Pessimistic Rank-Breaking (PRB) algorithm—an algorithm based on pessimism principle for offline decision making—can match the proposed lower bound.

4 - Self-Supervised Post-Training for Better LLM-Agent Decision-Making: a Regret-Minimization Approach

Chanwoo Park, MIT, Cambridge, MA, United States, Ziyang Chen, Asuman Ozdaglar, Kaiqing Zhang

Large language models (LLMs) are increasingly deployed as agents for interactive sequential decision-making tasks. Yet, despite their versatility, LLMs often struggle in dynamic, long-horizon environments such as full-information online learning, multi-armed bandits, contextual bandits, and Markov decision processes—frequently failing to exhibit desirable behaviors like effective exploration or low regret. To address this, we introduce *Self-Supervised Post-Training with Iterative Regret-Minimization*, a self-improving training algorithm that enhances LLM performance in sequential settings. Unlike conventional algorithm distillation, our approach avoids dependence on predefined expert policies or manually crafted language outputs. Instead, it instills a form of adaptive decision-making by jointly optimizing exploration-exploitation dynamics and regret minimization. Empirical results show that *Self-Supervised Post-Training with Iterative Regret-Minimization* consistently improves performance across a spectrum of models—from numerical self-attention agents and lightweight open-source LLMs to the more advanced GPT-4o-mini. Notably, models trained with *Self-Supervised Post-Training with Iterative Regret-Minimization* generalize robustly to out-of-distribution environments, including changes in action/state space size, reward sparsity or shift, and even semantically novel descriptions of real-world sequential tasks. Finally, we provide theoretical insight into why a single-layer attention mechanism—the backbone of many LLMs—can serve as a no-regret learner under our training objective, offering a principled understanding of its decision-theoretic properties.

Data-Driven Decision-Making in Online Marketplaces

Invited Session

Revenue Management

Chair: Chamsi Hssaine, University of Southern California, Marshall School of Business, Los Angeles, CA, United States

1 - The Data-Driven Censored Newsvendor Problem

Sean Sinclair, Northwestern University, Evanston, IL, United States, Chamsi Hssaine

We study a censored variant of the data-driven newsvendor problem, where the decision-maker must select an ordering quantity that minimizes expected overage and underage costs based only on offline censored sales data, rather than historical demand realizations. Our goal is to understand how the degree of historical demand censoring affects the performance of any learning algorithm for this problem. To isolate this impact, we adopt a distributionally robust optimization framework, evaluating policies according to their worst-case regret over an ambiguity set of distributions. This set is defined by the largest historical order quantity (the observable boundary of the dataset), and contains all distributions matching the true demand distribution up to this boundary, while allowing them to be arbitrary afterwards. We demonstrate a spectrum of achievability under demand censoring by deriving a natural necessary and sufficient condition under which vanishing regret is an achievable goal. In regimes in which it is not, we exactly characterize the information loss due to censoring: an insurmountable lower bound on the performance of any policy, even when the decision-maker has access to infinitely many demand samples. We then leverage these sharp characterizations to propose a natural robust algorithm that adapts to the historical level of demand censoring. We derive finite-sample guarantees for this algorithm across all possible censoring regimes and show its near-optimality with matching lower bounds (up to polylogarithmic factors). We moreover demonstrate its robust performance via extensive numerical experiments on both synthetic and real-world datasets.

2 - Learning Fair and Effective Points-Based Rewards Programs

Yichun Hu, Cornell University, Ithaca, NY, United States, Chamsi Hssaine, Ciara Pike-Burke

Points-based rewards programs are a prevalent model to incentivize customer loyalty; in these programs, customers who make repeated purchases from a seller accumulate points, working toward eventual redemption of a free reward. If implemented correctly, they can significantly increase revenue for the seller. However, these programs have recently come under scrutiny due to accusations of unfair practices. Motivated by these concerns, this paper studies the problem of fairly designing points-based rewards programs, focusing on two main obstacles that put fairness at odds with effectiveness. First, customer heterogeneity suggests that different redemption thresholds should be set for different customers to generate high revenue. Second, the relationship between customer behavior and the number of accumulated points is typically unknown, requiring experimentation that may devalue previously earned points.

We first show that an individually fair rewards program using the same threshold for all customers suffers at most a constant factor loss in revenue of $1 + \ln 2$, compared to the optimal personalized strategy. We then tackle the design of temporally fair learning algorithms under demand uncertainty. We propose a “stable” learning algorithm that only changes the redemption threshold $O(\log T)$ times over a horizon of length T , incurring $O(\sqrt{T})$ regret - optimal up to poly-logarithmic factors. We also modify this algorithm to only decrease thresholds, improving fairness at a cost of a constant factor in regret. Finally, extensive numerical experiments reveal the limited value of personalization in average-case settings and demonstrate the strong practical performance of our proposed algorithms.

3 - Satisficing Regret Minimization in Bandits: Constant Rate and Light-Tailed Distribution

Tianyi Ma, Cornell University, Ithaca, NY, United States, Qing Feng, Ruihao Zhu

Motivated by the concept of *satisficing* in decision-making, we consider the problem of satisficing regret minimization in bandit optimization. In this setting, the learner aims at selecting satisficing arms (arms with mean reward exceeding a certain threshold) as frequently as possible. The performance is measured by *satisficing regret*, which is the cumulative deficit of the chosen arm's mean reward compared to the threshold. We propose **SELECT**, a general algorithmic template for **S**atisficing **R**egret **M**inimization via **S**ampLing and **L**ow**E**r **C**onfidence **B**ound **T**esting, that attains constant satisficing regret for a wide variety of bandit problems in the realizable case (*i.e.*, a satisficing arm exists). Specifically, given a class of bandit problems and a corresponding learning oracle with sub-linear (standard) regret upper bound, **SELECT** iteratively makes use of the oracle to identify a potential satisficing arm with low regret. Then, it collects data samples from this arm, and continuously compares the LCB of the identified arm's mean reward against the threshold to determine if it is a satisficing arm. As a complement, **SELECT** also enjoys the same (standard) regret guarantee as the oracle in the non-realizable case. We also study the tail risk control in satisficing regret minimization. We modify **SELECT** and propose **SELECT-LITE** that attains a light-tailed satisficing regret distribution in the realizable case. **SELECT-LITE** also enjoys a constant expected satisficing regret in the realizable case and a sub-linear expected standard regret in the non-realizable case. Finally, we conduct numerical experiments to validate the performance of **SELECT** for several popular bandit settings.

4 - Optimal Incentive Design for Decentralized Dynamic Matching Markets

Pengyu Qian, Boston University, Boston, MA, United States, Chen Chen, Jingwei Zhang

In decentralized dynamic matching markets, agents can benefit from sharing resources, but they will collaborate only if properly incentivized. Motivated by applications such as multi-hospital kidney exchanges and job-hunting markets, this paper proposes novel monetary and non-monetary mechanisms to incentivize collaboration in such decentralized dynamic markets. We study a model in which multiple self-interested agents manage local multi-way dynamic matching problems. Jobs of different types arrive stochastically at each agent, expire after a limited time, and yield rewards when matched. An agent's job backlog and actions are her private information, and each agent aims to maximize her long-run average matching reward.

We design simple mechanisms that incentivize agents to submit all jobs upon arrival, thereby enabling centralized matching. Our first mechanism, the Marginal-Value (MV) mechanism, reimburses agents based on the marginal value of their submitted jobs. This can also be implemented in a non-monetary way by randomly selecting an agent (with a specified probability) to perform a match and collect the associated matching reward. We show that under the MV mechanism, full job submission constitutes an approximate Nash equilibrium—that is, the gain from unilateral deviation vanishes as the number of agents grows. To further eliminate incentives for deviation, we propose a refined mechanism, the Marginal-Value-plus-Credit (MVC) mechanism, and show that when the number of agents exceeds a constant threshold, full job submission constitutes a stronger oblivious equilibrium. Numerical experiments based on kidney exchange data demonstrate that the gains from deviation under our mechanisms are small even in moderately sized markets.

Algorithms and Fairness in Mechanism and Market Design

Invited Session

Auctions and Market Design

Chair: Emily Diana, Tepper, Pittsburgh, PA, United States

1 - Designing Personalized and Equilibrium-Aware Recommendations for School Matching

Erica Chiang, Cornell Tech, New York, NY, United States, Kenny Peng, Nikhil Garg

In New York City, students from underserved communities disproportionately apply to and enroll in high schools with lower metrics such as performance, impact, graduation rate, and selectivity. Existing work suggests this may be due to factors including application complexity, the time cost of forming preferences over many (800+) schools, and unequal access to information—all of which tend to favor more resourced, well-connected families.

Inspired by this setting, we study how to design a recommendation-based informational intervention to help students make more informed decisions about school options. In this talk, I will discuss our approach to designing fair, personalized recommendations that remain effective in equilibrium—the setting where all students receive recommendations at the same time and may change their behavior accordingly.

2 - Improved Algorithms for Fair Matroid Submodular Maximization

Sherry Sarkar, Carnegie Mellon University, Pittsburgh, PA, United States

Submodular maximization subject to matroid constraints is a central problem with many applications in machine learning. As algorithms are increasingly used in decision-making over datapoints with sensitive attributes such as gender or race, it is becoming crucial to enforce fairness to avoid bias and discrimination. Recent work has addressed the challenge of developing efficient approximation algorithms for fair matroid submodular maximization. However, the best algorithms known so far are only guaranteed to satisfy a relaxed version of the fairness constraints that loses a factor 2, i.e., the problem may ask for ℓ elements with a given attribute, but the algorithm is only guaranteed to find $\lfloor \ell/2 \rfloor$. In particular, there is no provable guarantee when $\ell=1$, which corresponds to a key special case of perfect matching constraints.

In this work, we achieve a new trade-off via an algorithm that gets arbitrarily close to full fairness. Namely, for any constant $\epsilon > 0$, we give a constant-factor approximation to fair monotone matroid submodular maximization that in expectation loses only a factor $(1-\epsilon)$ in the lower-bound fairness constraint. Our empirical evaluation on a standard suite of real-world datasets -- including clustering, recommendation, and coverage tasks -- demonstrates the practical effectiveness of our methods.

3 - Minimax Group Fairness in Strategic Classification

Emily Diana, Tepper, Pittsburgh, PA, United States

In strategic classification, agents manipulate their features, at a cost, to receive a positive classification outcome from the learner's classifier. The goal of the learner in such settings is to learn a classifier that is robust to strategic manipulations. We consider learning objectives that have group fairness guarantees in addition to accuracy guarantees. We work with the minimax group fairness notion that asks for minimizing the maximal group error rate across population groups.

We formalize a fairness-aware Stackelberg game between a population of agents consisting of several groups, with each group having its own cost function, and a learner in the agnostic PAC setting in which the learner is working with a hypothesis class H . When the cost functions are separable, we show the existence of an efficient algorithm that finds an approximately optimal deterministic classifier for the learner when the number of groups is small. This algorithm remains efficient, both statistically and computationally, even when H is the set of all classifiers. We then consider cost functions that are not necessarily separable and show the existence of oracle-efficient algorithms that find approximately optimal randomized classifiers for the learner when H has finite strategic VC dimension. These algorithms work under the assumption that the learner is fully transparent: the learner draws a classifier from its distribution (randomized classifier) before the agents respond by manipulating their feature vectors. We highlight the effectiveness of such transparency in developing oracle-efficient algorithms and conclude by verifying the efficacy of our algorithms on real data.

4 - Settling the Competition Complexity of Additive Buyers over Independent Items

Eric Xue, Princeton University, Princeton, NJ, United States

Unlike single-dimensional revenue maximization solved by Myerson (1981), the optimal auction for selling multiple heterogeneous items remains elusive. Over the past two decades, significant progress has been made in designing simple auctions that achieve a constant fraction of optimal revenue. However, a constant fraction may not suffice in some applications, and in others, learning bidder distributions accurately enough is costly.

Bulow and Klemperer (1989) introduced a prior-independent approach, showing that the second-price auction with one extra bidder outperforms the optimal single-item auction without that bidder. Inspired by this, recent work in multi-dimensional settings introduced the notion of *competition complexity*: the number of extra bidders required so that selling items separately with these bidders yields more revenue than the optimal complex mechanism without them.

Previous results determined the competition complexity for n bidders with additive values over $m > n$ independent items as $\Theta(n \log(m/n))$. Our main result settles the open case where $m < n$: we show the competition complexity is $\Theta(\sqrt{nm})$. The $O(\sqrt{nm})$ upper bound was established by Beyhaghi and

Weinberg (2019); we strengthen their lower bound from $\Omega(\ln n)$ to $\Omega(\sqrt{nm})$.

Our proof relies on an explicit construction of a Bayesian IC auction for n bidders with additive values over $m < n$ independent items from the truncated Equal Revenue distribution. This construction achieves revenue exceeding that of selling each item separately to $n + \sqrt{nm}$ bidders, thereby tightly characterizing competition complexity in this regime.

5 - Learning by Climbing: Incentives and Fairness of Upskilling

Guanting Wu, Carnegie Mellon University, Pittsburgh, PA, United States, Peter Zhang, Hai Wang

Problem Definition: Online labor markets (OLMs) are growing rapidly, where platforms recommend matches between clients and workers to ensure project completion and satisfactory *service quality*. Service quality is influenced by worker-project skill compatibility, worker skill levels, and the heterogeneity of their interactions. Due to non-standard match recommendation policies and intrinsic data limitations, quantifying the influence of these determinants on service quality is technically challenging but critical. We propose an empirical approach to understand how workers develop diverse skills by doing different gigs and how such diversity influences service quality, especially when workers focus on a limited set of categories.

Methodology/Results: We develop a partially observable Markov process (POMP) framework instantiated as a multivariate linear-Gaussian model to track latent skill development and its impact on service quality. A two-stage solution approach is proposed to estimate model parameters from a proprietary large-scale dataset with millions of transactions over 12 months. We find that skill development within a category follows a concave growth trajectory, worker-project skill compatibility significantly affects service quality, and project complexity—reflected in contract form, duration, and price—adversely impacts it.

Managerial Implications: Platforms should adopt growth-trajectory-aware and category-aware recommendation systems and consider project decomposition. NLP techniques could analyze dynamic text data to improve service quality. Our estimation framework is also applicable to other matching settings, such as online dating platforms, featuring dynamic and non-standard recommendation policies.

1 - The Impact of Premium Licenses on Creator Behavior

Jae Sang Rhee, Georgia Institute of Technology, Atlanta, GA, United States, Mingfeng Lin

Creator economy relies on third-party, free-sharing platforms, which enable creators to reach wide audiences, enhancing monetization opportunities. However, creators remain uncompensated, visibility declines due to oversaturation, and unauthorized use of their work poses risks, especially as AI training datasets frequently source freely accessible content. These issues harm both creators and platforms. Some platforms introduced a premium license, offering subscription-based exclusive content, upfront payments, and enhanced copyright protection. This paper investigates the impact of premium licensing on creator behavior by leveraging a natural experiment. Using data from Unsplash and Pexels, we find that premium licenses on free-sharing platforms reduce the volume of freely available content by 13.2%, even among creators without license access who are not directly affected. We identify two mechanisms driving this decline. First, reduced multi-homing occurs as creators deactivate accounts and move away from the licensed platform. Second, creators improve free content quality to compete with premium offerings. These trades-offs reveal unintended effects on both content volume and quality, affecting creators and platforms alike. Consequently, effective monetization policies must balance platform revenue with a healthy content ecosystem and creators' branding goals. Premium licensing signals a broader shift from open to closed access, reshaping how content is produced and consumed. As AI heightens the need to safeguard creative work, understanding these dynamics becomes increasingly urgent, calling for further research into premium licensing and its role in the evolving creator economy.

2 - How Prospective Accounting Bias Impacts Streaming Media Consumption

Yifei Wang, University of New Hampshire, Durham, NH, United States, Maya Mudambi

In the streaming era, consumers can subscribe to platforms like Netflix, which offer access to a library of titles for a subscription fee, or rent/purchase individual titles. According to prospective accounting theory (Prelec & Loewenstein, 1998), payment method and timing shape consumer behavior. This study examines how subscription models influence consumption on a platform offering both payment structures, contributing to research on mental accounting, streaming, and platform strategy. Using a staggered difference-in-differences approach, we exploit the timing of films shifting from rental-only to subscription. Subscription access increases overall consumption and exploratory viewing but lowers average ratings. Content led by women and people of color sees a greater viewership boost, suggesting stronger engagement with marginalized voices. Robustness checks support prospective accounting bias as the key mechanism, ruling out alternative explanations. Future work will further quantify exploratory viewing and examine how pricing models interact with historical media preferences across multiple dimensions.

3 - From Disruption to Dialogue: Professional Discourse on Social Media on Emerging Technologies

Yupei Hu, University of Pittsburgh, Pittsburgh, PA, United States, Priyanga Gunarathne, Xiaomeng Chen, Narayan Ramasubbu

This study explores the evolution of professional discourse around a disruptive technology within a physician community on X (formerly Twitter), focusing on its emergence and progression toward an AI-empowered medical specialty. Drawing on a comprehensive dataset of all professional interactions among physicians in this community over a six-year period, we adopt a mixed-methods approach—combining social network analysis, topic modeling, and temporal discourse analysis—to trace how this technology entered professional conversations, gained momentum, and ultimately intersected with narratives around artificial intelligence. By mapping the dynamics of influence, adoption, and thematic shifts, the study offers novel insights into how disruptive technologies diffuse and evolve within professional digital communities. The findings contribute to the literature on digital transformation in healthcare, technology adoption among professionals, and the role of social media in shaping innovation trajectories.

4 - Strategic Visuals: Metaphorical Design and Viewer Emotion in Vi Marketing

Ying Wang, Northern Illinois University, Naperville, IL, United States, Jaeki Song

As virtual influencers (VIs) become increasingly prominent in digital marketing, understanding how their visual design influences audience emotions is essential. Drawing on Conceptual Metaphor Theory and Visual Rhetorical Theory, this study investigates how different types of visual metaphors affect emotional engagement in VI-based video campaigns. We analyzed 100 YouTube videos featuring virtual influencers using computer vision (YOLO) to classify visual metaphors and natural language processing to assess viewer sentiment and influencer-product alignment. This study contributes to marketing and information systems fields by extending metaphor research into dynamic video contexts and highlights the critical role of symbolic coherence and design in VI marketing. Practically, the study offers actionable insights for brands and content creators on how to craft emotionally compelling virtual influencer content through effective metaphorical storytelling and strategic alignment.

1 - Optimization Models for the Sand-Casting Processes in Foundries

Hajar Zegrati, University of Brescia, Brescia, Italy, Luca Bertazzi

We study a complex real-life industrial scheduling problem concerning the melting process in a foundry industry using sand casting. For this problem, we formulate a mixed integer linear programming formulation able to overcome a previous non-linear model. The main challenge is the complexity in handling the residual liquids that are reused in subsequent castings if the same type of alloy is being produced. The setup costs are represented by the change of alloy that requires the emptying of the furnace from the previously processed alloy and therefore depend on the sequence of production. Moreover, we introduce goal programming to find the best balance between different objectives, in terms of total cost, energy consumption, and pollution, considering that foundries are responsible for one third of global energy consumption and a quarter of greenhouse gas emissions. Extensive computational results show that the new model is able to find better solutions than the previous one in short computational time and better balanced solutions in terms of total cost, energy consumption, and pollution.

2 - An Adp Algorithm for Dynamic Steel-Making Scheduling Problem Considering Ladle Assignment

Yuxuan Zhang, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Ying Meng, Lixin Tang

In steel-making workshops, heats are scheduled according to their production routes. The feasibility of the schedule is greatly affected by the uncertain availability of ladles, the containers of molten steel during production. In the worst cases, the production procedure would even be interrupted. In this paper, we investigate a dynamic steel-making scheduling problem considering the feasible assignment-timetabling of ladles under uncertain production durations. To illustrate the problem, we develop an MIP formulation based on perfect information. While the existing research literature has been focusing on finding a dynamic strategy that minimizes the expected value of the objectives enacted, our problem emphasizes the performance under the worst-case scenario in this stability-focusing production environment. Specifically, the problem is formulated as a Markov decision process that applies a robust optimization paradigm at each decision epoch. To address this problem, we develop an effective approximate dynamic programming (ADP) algorithm, which relies on look-ahead simulations based on Monte Carlo sampling and a decision rule-based ladle assignment strategy. Computational results on the random instances show that our ADP algorithm can obtain competitive solutions with the greedy algorithms in a reasonable computational time and prove the robustness against uncertainty.

3 - Exact Algorithm for Plate Design Problem with Uncertain Trim Loss in Steel Enterprises

Sen Li, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Ying Meng, Lixin Tang

In the steel plate production process, slabs are rolled into wide and thin raw plates, which are then cut into smaller plates to meet customer demands. Effective plate design is critical for improving material utilization. However, fluctuations in equipment performance usually introduce uncertainty in trim loss, leading to deviations from the design plan and resulting in material waste. We study a plate design problem under uncertain trim loss, which is modeled as a two-dimensional, two-stage guillotine cutting stock problem with knapsack-type uncertainty. A budget uncertainty set is adopted to describe the uncertain trim loss. Then, we formulate the problem as a set covering model, which is further reformulated into a deterministic equivalent. An adapted branch-and-price algorithm is developed for the obtained deterministic cutting stock problem. Furthermore, we propose a tailored solution approach for the two-stage subproblem and design an exact labeling algorithm to solve it optimally. Computational experiments demonstrate that our method significantly improves material utilization and enhances robustness compared to traditional approaches.

4 - A Two-Stage DRO Approach for Production Planning with Correlated Machine Breakdown

Qingyang Wang, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Ying Meng

We develop a two-stage distributionally robust optimization (DRO) framework for the production planning problem under uncertain machine breakdowns (PPUMB). In the first stage, material allocations are determined; in the second, production plans are optimized in response to potential machine breakdown scenarios. Instead of assuming independent machine breakdowns, we consider correlated breakdowns across machines and model machine breakdowns using joint probability distributions, which better reflects real-world production environments. We prove that the second-stage expected objective function is supermodular, and leverage this structural property to derive the worst-case distribution and reformulate the DRO model into a deterministic equivalent. This reformulation introduces substantial computational complexity due to the increase in variables and constraints. To address this, we design a tailored multicut Benders decomposition (MBD) algorithm. Additionally, we incorporate supervised learning into the solution process by training a classifier to identify and retain only high-quality optimality cuts, thereby improving computational efficiency. Experiments based on real production data demonstrate that the proposed approach significantly reduces solution time and yields robust, high-quality production plans under uncertainty.

5 - Integrated Order Acceptance, Production Scheduling, and Distribution In Additive Manufacturing with Energy Consumption and Material Recycling Considerations

Fatemeh Pourdehghan, University of Missouri, Columbia, MO, United States, Omid Shahvari, Sharan Srinivas

This study addresses a problem of integrated order acceptance, production scheduling, and delivery routing for additive manufacturing (AM) systems using selective laser melting (SLM). AM shifts production from "make-to-stock" toward customized and make-to-order items, printed only after an order is confirmed. Integrating production and delivery in 3D printing is essential, as ignoring delivery constraints causes production scheduling to focus solely on production objectives, like grouping orders by material. This results in high delivery costs if customers are far apart. A key advantage of SLM is its ability to reuse remaining material from previous batches, enhancing material efficiency and reducing waste. By considering material-specific refresh rates, we aim to improve the overall sustainability and cost-effectiveness of the process. The production stage involves batch processing of parts on unrelated parallel AM machines with material eligibility constraints. Once production is complete, parts are regrouped into delivery batches- independent of the initial batches- and delivered to customers using heterogeneous vehicles. Each vehicle performs one trip, and routing follows vehicle routing problem (VRP) framework. The objective is to maximize total profit, defined as total revenue minus relevant costs, including material waste, setup, tardiness, energy consumption, and transportation. To the best of our knowledge, this is the first study to jointly optimize order acceptance, AM-based production scheduling, and VRP, while incorporating energy consumption and material recycling. We propose a mixed-integer linear programming (MILP) model for small-sized instances and an Adaptive Large Neighborhood Search (ALNS) for large-sized problems. Computational experiments highlight the effectiveness of the proposed algorithm.

6 - Balancing Risk and Repairs: A Consumer-Driven Model for Electronics Repair Support Duration

Meltem Denizel, Iowa State University, Ames, IA, United States, Haley Paluzzi

Designing electronics with repairability in mind can extend product lifespans, which improves resource efficiency and promotes sustainability. However, repair rates for used electronics in the United States remain low, with most consumers choosing to replace damaged items rather than repairing them. The purpose of this study is to explore how consumer perceptions of risk influence their willingness to engage in product repairs. By understanding how willingness to pay for repairs changes over time, we can develop a model to predict the optimal duration for offering repair services. Therefore, this study seeks to address two research questions: (1) What is the nature of the relationship between the expected product lifespan and willingness to pay for product repairs over time? and (2) How do decreasing rates in willingness to repair impact the ideal length of time that repair services should be offered?

7 - Power Simulation for Milling Based on a Generalized Model Incorporating Tool Wear and Material Properties

JinGoo Jeong, Kyung Hee University, Yongin-si, Korea, Republic of, Ga Hyun Lee, Byunghun Song, Hyun Woo Jeon

Enhancing energy efficiency in manufacturing is critical for both addressing climate change and optimizing operational performance. Among various machining processes, milling is particularly energy-intensive, making accurate power prediction essential for effective energy management. Traditional power models based on material removal rate (MRR) often disregard tool wear, a significant driver of power variation over time. While several prior studies have attempted to incorporate tool wear, their applicability is frequently limited to specific materials or experimental setups. To overcome these limitations, this study proposes a dynamic power model that generalizes across diverse manufacturing conditions by integrating tool wear and workpiece material hardness as core variables. We implement this model in a discrete event simulation (DES) framework and evaluate power consumption time series across three distinct workpiece materials—aluminum alloy, stainless steel, and titanium alloy. The simulation results indicate that titanium alloy, the hardest material, leads to the highest average power and energy consumption, while aluminum alloy, the softest, shows the highest peak power due to prolonged tool wear effects. In addition, the results are analyzed using multiple comparison criteria such as replacement frequency and power fluctuations. These findings demonstrate the complex interaction between tool wear and material hardness in shaping power demand. The proposed model facilitates more realistic and scalable energy analyses, contributing to informed decision-making for sustainable manufacturing.

1 - Catch Me if You Can: An Optimal Pest Survey Strategy to Delimit Biological Invasions

Spencer Hill, Department of Mathematics and Statistics, Queen's University, Kingston, ON, Canada, Jue Wang, Denys Yemshanov

We consider the problem of optimal allocation of limited resources to delimit the frontier of the spread of an invasive species population. Given a fixed sampling budget and an invasive species detection rate and linear population spread rate, we formulated the delimiting survey problem as a partially observable Markov decision process (POMDP) where the objective is to minimize the cumulative gap between the unobservable (true) infestation frontier and the closest location with a detected infestation. We proved that the resulting POMDP problem can be equivalently formulated and solved as a deterministic optimal control problem. In the simplest case of two sampling locations, we used Pontryagin's maximum principle to describe the optimal sampling strategy. The optimal control is heavily influenced by the survey budget level; for any budget level greater than twice the ratio between the spread and detection rate, it is optimal to sample only at the closest site to the previously detected infestation. In a general case of N survey sites, we applied a discrete-time numerical approximation to compute a near-optimal sampling strategy. We evaluated the surveillance strategies for four species with distinct combinations of detection and spread rates. Our work provides pest management practitioners with practical insights for developing heuristic sampling strategies to maximize the capacity to delimit the spreading pest invasion frontier.

2 - Multi-Stakeholder Public-Private Partnerships (MSPs) in Health Emergencies

Ioanna Falagara, Vienna University of Economics and Business, Vienna, Austria, Evelyne Vanpoucke, Adam Abdelsalam

Multi-Stakeholder Partnerships (MSPs) play a vital role in responding to global health emergencies. By leveraging the complementary strengths of the public and private sectors and collective actions, MSPs help ensure the timely and equitable distribution of essential medical resources during health emergencies.

This research investigates how stakeholder salience shapes the structure and function of MSPs formed in response to global health crises. Applying the three dimensions of stakeholder salience—power, legitimacy, and stake—the research evaluates how various actors influence the formation and operational dynamics of MSPs. The findings highlight the diverse contributions of stakeholders and reveal how disparities in salience impact decision-making processes, governance structures, and resource allocation within MSPs.

3 - Assessing the Assumptions of Vehicle Dispatch Timing in a Disaster-Relief Supply Chain Network

Robert Cook, Northeastern Illinois University, Chicago, IL, United States

This study assesses the impact of one key assumption from the seminal work in the Disaster Relief Logistics literature regarding the timing of dispatch decisions between a Staging Area and the Point of Distribution in a Last Mile Distribution context. We compare versions of the model where beneficiaries wait until the end of a decision period before leaving the Point of Distribution and where they vacate immediately after receiving as much inventory is available. Similar to previous studies, continuously dispatching the vehicle (CD) is shown to be an optimal or nearly-optimal policy in the majority of conditions tested, and even narrowed the gap to the optimal policy previously shown in literature. Therefore, CD is the best available decision policy for practical use.

4 - Dynamic Outbreak Countermeasure Logistics

Mohsen Mehrabiyan, West Virginia University, Morgantown, WV, United States, Zeyu Liu

The effective deployment of medical countermeasures (MCMs) is critical to strengthening national readiness against epidemic outbreaks. However, uncertain demand, supply shortage, and unequal distribution of healthcare resources have complicated MCM deployment planning for practitioners. In this study, we develop a multi-stage stochastic programming (MSP) model to optimize facility location, resource allocation, and dynamic MCM deployment decisions under uncertainty. We further improve the MSP model by embedding vehicle routing constraints and equitable resource distribution constraints. Due to the complexity of solving large-scale problems, we employ Nested Benders Decomposition (NBD) and design an improved Progressive Hedging (PH) algorithm. Artificially generated outbreak scenarios are used as benchmarks to test algorithm performances. The model is then calibrated with real-world COVID-19 transmission and capacity data from the state of West Virginia to evaluate the practical impact of vehicle routing and equitable distribution decisions. The case study highlights clear trade-offs between delivery speed, cost, and fairness, offering practical guidance to public health practitioners.

5 - Designing a Sustainable Vaccine Supply Chain by Considering Demand Substitution and Value-Added Function During a Pandemic Outbreak

Samira Alsadat Salari, University of Arkansas, Fayetteville, AR, United States

Pandemics like COVID-19 impose serious social, economic, and health burdens, prompting governments to enhance national resilience through effective vaccination strategies. Some countries rely on both domestically produced vaccines and international aid, necessitating the development of a sustainable and responsive vaccine supply chain. This study incorporates vaccine-specific efficacy and shelf life, based on established literature, to address the perishability and performance of different brands. Recognizing that vaccine shortages are common during pandemics due to procurement, distribution, and storage constraints, we examine demand substitution based on relative efficacy to mitigate unmet demand and reduce infection rates. The model also integrates both permanent vaccination sites (e.g., hospitals and clinics) and mobile centers to improve accessibility and coverage across diverse geographic and demographic populations. A multi-objective mathematical model is formulated and solved using the augmented ϵ -constraint method. A real-world case study demonstrates the model's applicability. Results and sensitivity analysis reveal that combining fixed and mobile vaccination centers enhances service delivery, while demand substitution offsets approximately 60% of shortages, accelerating immunization efforts.

Chair: Timothy Anderson, Portland State University, Portland, OR, United States

1 - Accuracy and/OR Explainability? the Deployment and Adoption of Generative Ai with Hallucinations**Xu Zhang, School of Management, Fudan University, Shanghai, China, People's Republic of, Siyi Yang, Yifan Dou, Cheng Zhang**

Generative AI tools promise significant productivity gains but are hindered by a persistent challenge: **hallucinations**—outputs that include false or misleading information presented as facts. This paper examines how organizations can strategically deploy AI tools when such hallucinations exist, particularly focusing on two key levers: improving the **model accuracy** (reducing hallucination frequency) and enhancing the **output explainability** (lowering verification costs). We develop a game-theoretic model in which a principal provides generative AI to an agent tasked with completing a quality-sensitive assignment. The agent decides whether to adopt the AI, whether to verify its output, and whether to invest further effort in improving its quality. We show that accuracy and explainability share a dynamic, non-monotonic relationship: when accuracy is low, explainability serves as a substitute by reducing verification cost and encouraging responsible AI use. When accuracy is high, the two act as complements, jointly necessary to avoid free-riding behavior. These findings challenge the conventional wisdom that explainability and accuracy can be treated as simple substitutes. We further consider some forms of explainability provide supportive justifications for AI-generated content—regardless of whether it is correct—which may mislead users' judgment. We examine how users with varying discernment capabilities respond to Gen-AI outputs accompanied by the explanations. Our results inform how firms should balance technical improvements with user-interface design to achieve high-quality outcomes. By modeling both sides of AI deployment—technical design and user adoption—our research offers managerial supports for deploying trustworthy AI and contribute to the economic understanding of technology adoption.

2 - Unlocking the Value of Custom AI: The Role of Proprietary Resources**Xiaoyang Zhen, IE Business School, Madrid, Spain, Fabrizio Salvador**

Large language models are spawning a new generation of custom AI agents that combine generic model capabilities with task specific data, tools, and workflows. Yet we know little about whether the proprietary resources — domain knowledge bases, private plugins, and structured workflows—actually make these agents more valuable. We address this gap by analyzing over 400,000 agents created on an AI platform, one of the world's largest no code agent platforms. Leveraging platform telemetry with detailed agent-configuration records, we estimate the causal effect of proprietary resource adoption on agent success using an instrument variable strategy and category fixed effects models. This study aims to contribute to the platform ecosystem literature by highlighting proprietary resources as critical yet underexplored factors in decentralized AI development. The insights offer practical implications for developers and platform managers in designing resource integration strategies to optimize the value generation of AI agents.

3 - Decoding Individuals' Resistance Toward GAI Adoption in the Workplace**Neda Khosh Kheslat, University of North Texas, Denton, TX, United States**

As one of the most revolutionary technologies, generative AI adoption in an organizational setting is essential for improving performance and raising work productivity. However, previous studies in the change management field have consistently shown that user resistance plays a significant role in adopting new information technology. This study aims to determine factors influencing employee resistance to adopting GAI technologies in the workplace through an integrative framework inspired by innovation resistance theory (IRT) and the status quo bias perspective. This study also takes a unique and nuanced approach regarding the function of GAI models capable of autonomy, decision-making, and learning.

4 - Perceptions and Usage of Gen AI Chatbots - A Meta-analytic Systematic Review**Suchitra Veera, Snayu, Fort Worth, TX, United States, Pranav Veera**

Chat GPT and similar Generative Artificial Intelligence (Gen AI) technologies (Llama, Gemini, etc.) that are based on Large Language Models (LLMs) have been gaining rapid adoption in some areas of business recently. The use of chatbots is one of the highlights of the implementation of these Gen AI models for serving the needs of customers for companies in the roles of call center agents, marketing content developers, as well as for educational tutoring. This presentation will discuss the findings from a systematic review study of previous empirical research to develop a better understanding of how Gen AI usage is gaining adoption in the form of a variety of chatbot-based products and services. Using a meta-analytic approach this research will provide insights into the perceptions and usage of Gen AI technology-based products such as chatbots. The meta-analysis is based on data gathered from prior empirical studies conducted by researchers over the past five years. The results from the findings of the meta-analysis on the perceptions and usage of chatbots provide details of the variability of effect sizes across studies, estimate of the population effect size with associated confidence interval, moderator variables that can explain the variability, and publication bias in the studies. Such an analysis provides an understanding of the areas of growth and demand in the use of chatbots and use cases where adoption is lagging. These insights can help to steer the development of such chatbot-based products that are more effective and serving the needs of customers better.

5 - Technology Forecasting of AI LLMs**Timothy Anderson, Portland State University, Portland, OR, United States**

Presentation will provide initial results of using TFDEA, Technology Forecasting Using Data Envelopment Analysis of generative AI LLM platforms.

Small-Sample Machine Learning and its Applications in Smart Manufacturing

Invited Session

Quality, Statistics and Reliability

Chair: Weizhi Lin, San Jose State University, San Jose, CA, United States

Co-Chair: Qiang Huang, University of Southern California, Los Angeles, CA, United States

1 - Quantum Bayesian Optimization for Quality Improvement in Fuselage Assembly**Jiayu Liu, Rensselaer Polytechnic Institute, Green Island, NY, United States, Yinan Wang**

Recent efforts in smart manufacturing enhanced aerospace fuselage assembly processes, particularly by innovating shape adjustment techniques to minimize dimensional gaps between assembled sections. Existing approaches, including reinforcement learning or Bayesian optimization with surrogate models, have shown promising results but face limitations such as sensitivity to measurement noise and being extremely data-demanding (low sample efficiency). The development of quantum computing shed light on revolutionarily resolving the aforementioned challenges. We propose a Quantum Bayesian Optimization (QBO) framework for precise shape control during assembly. Specifically, this approach utilizes a quantum oracle based on finite element analysis (FEA)-based models or surrogate models, to acquire more accurate observations with fewer queries for a certain input. QBO employs an Upper Confidence Bound (UCB) acquisition function to strategically select input values that are most likely to minimize the gap. It has been theoretically proved to require much fewer samples while maintaining comparable optimization results. In the case study, QBO is applied to optimize force-controlled actuators for adjusting the shape of fuselage sections and reducing the gap to the adjoining section. Experimental results demonstrate that QBO achieves apparently lower cumulative regret compared to classical methods, particularly under noisy measurement conditions, with significantly fewer samples queried from the simulation.

2 - Adaptive Generative Modeling with Continual Learning for Data-Scarce Manufacturing**Mengfei Chen, The State University of New York at New Paltz, New Paltz, NY, United States, Vidita Gawade**

Manufacturing processes continually evolve to accommodate new products, tool variations, and shifting operating conditions, resulting in mixed, heterogeneous, and often anomalous data. This variability makes it difficult for static quality prediction models to generalize across tasks. A key challenge is data scarcity, caused by the infrequency of defects and the constant introduction of new product types, leading to limited historical data and highly imbalanced datasets, both of which degrade model

performance. While data augmentation is often used to address imbalanced data, many methods produce physically unrealistic synthetic data, undermining predictive accuracy despite advanced model architectures. To address these challenges, this study proposes an adaptive generative modeling framework integrated with continual learning. The approach synthesizes physics-constrained, physically valid in-process sensor data to balance datasets while employing continual learning in the generative model to adapt to evolving manufacturing scenarios. The method is validated through two case studies: porosity prediction in laser metal deposition and quality prediction through thermal images in the hot stamping process.

3 - Physics-Informed Cross-Modality Transfer Learning in Diffusion Models for Data Augmentation in Metal-Based Additive Manufacturing

Wenmeng Tian, Mississippi State University, Mississippi State, MS, United States, Hugo Rodriguez

Anomaly detection and in-situ monitoring are essential in additive manufacturing (AM) quality control. Artificial intelligence (AI) approaches can be used to leverage AM process data for quality improvements. However, limited data availability is one of the challenges in the applications of AI techniques in AM. Generative models (GMs) can be leveraged for data augmentation, enabling model performance improvement. Nevertheless, these models still require a sufficiently large dataset to generate high-quality synthetic samples. In AM, data collection can be very costly and time consuming. Therefore, transfer learning (TL) can be used to leverage publicly available datasets as source datasets, to transfer the knowledge obtained from the source domain to the target domain with a small-scale dataset. However, the high diversity of sensors for data collection in both source and target domains makes the transfer of knowledge across different sensor modalities more challenging. Therefore, a cross-modality transfer learning approach is proposed by leveraging a publicly available dataset of AM melt-pool optical images to improve the generative capabilities of a Denoising Diffusion Implicit Model (DDIM) by implementing model-based TL for data augmentation of AM thermal history. The real-world case study shows that the proposed approach enhances the performance of thermal image generation, especially when there is limited target data available.

4 - Domain-Informed Spatial Function Prediction on Surface Manifolds for Capturing Manifold-to-Manifold Variability

Weizhi Lin, University of Southern California, Los Angeles, CA, United States, Qiang Huang

Models for predicting spatial functions typically capture the correlations between covariates and scalar fields defined on a fixed surface manifold. However, the embeddings of surface manifolds may vary in practice, including both their intrinsic geometries and extrinsic positions in three-dimensional space. This manifold-to-manifold variability introduces complex spatial patterns and challenges accurate modeling of covariate effects with limited data. To address this, we propose decomposing spatial functions to characterize the variability introduced by intrinsic geometry and extrinsic position. The variability driven by intrinsic geometry is captured by the number and locations of critical points, which correspond to local high-order spatial patterns and remain invariant to extrinsic positioning. Meanwhile, the variability induced by extrinsic position is captured by local high-order spatial patterns whose locations are unrelated to the surface's internal structure. The shapes and locations of these high-order patterns are automatically identified and estimated using domain-informed adaptive Gaussian kernel bases. To enable prediction of complex spatial functions on a new manifold, we establish separate models for the intrinsic-driven, extrinsic-driven high-order patterns and smooth low-order patterns. For each component, a greedy best subset selection is performed to identify the most relevant covariates, which are then modeled with a generalized functional additive mixed model. We demonstrate the effectiveness of the proposed methods through a real-world case study on modeling surface deviations of 3D-printed objects. With limited samples, the method accurately predicts complex surface deviation patterns for parts printed at different locations on the print bed.

5 - Identification of Latent Invariant Surface Quality Patterns via Spatial Stochastic Process Deformation

Minghao Gu, University of Southern California, Los Angeles, CA, United States, Qiang Huang

Surface quality characterization is important for ensuring product functionality and guiding production. Although a wealth of literature has been developed for mass production, unique challenges arise in additive manufacturing (AM) because of the one-off fabrication of a wide range of complex geometries. Surface quality patterns can change with built geometries and covariates such as shape size and built location. Existing statistical characterization methods are therefore not adaptive to AM due to frequent design changes and insufficient samples for each design. Since a product can be represented by a finite type of surface patches, this initial study investigates the surface quality of products with spherical patches. We propose to identify latent and invariant patterns to characterize surface quality by separating the effect of covariates. The surface quality of different domes is first described by nonstationary spatial Gaussian processes. These heterogeneous spatial stochastic processes are then mapped to one underlying base process through a spatial stochastic process deformation method. With covariate effects fully captured by the mapping function, the underlying base process characterizes the latent invariant surface quality patterns of spherical patches and the working status of the machine. Actual printed samples from an AM process are utilized for methodology demonstration. The study brings the prospect of evaluating and comparing product surface quality and process condition in one-off AM.

Co-Chair: Kaibo Liu, UW-Madison, Madison, WI, United States

1 - Sequential Conformal Prediction for TIME Series with Uncertainty Quantification

Hanyang Jiang, Georgia Institute of Technology, Atlanta, GA, United States

Conformal prediction (CP) has been a popular method for uncertainty quantification because it is distribution-free, model-agnostic, and theoretically sound. For forecasting problems in supervised learning, most CP methods focus on building prediction intervals for univariate responses. In this work, we develop a sequential CP method called MultiSPCI that builds prediction regions for a multivariate response, especially in the context of multivariate time series, which are not exchangeable. Theoretically, we estimate finite-sample high-probability bounds on the conditional coverage gap. Empirically, we demonstrate that MultiSPCI maintains valid coverage on a wide range of multivariate time series while producing smaller prediction regions than CP and non-CP baselines.

2 - Deep Belief Updater Model for Coupled Higher-Order Hidden Semi-Markov Chains

Vipul Bansal, University of Wisconsin Madison, Madison, WI, United States, Shiyu Zhou

We propose a Deep Belief Updater (DBU) Model to address the challenge of modeling complex temporal dependencies in Coupled Higher-Order Hidden Semi-Markov Chains. These models extend Higher-Order Hidden Semi-Markov Chains by incorporating temporal dependencies among hidden states across multiple interdependent chains. Replacing underlying temporal dynamics with neural networks is computationally intensive, as it requires updating the state history at each time instance for each chain, based on the history of all the chains. To overcome this, we find that forward-state probabilities, the probabilities of being in a given state at a time instance based on the history of observations, can be expressed as a function of the Stage I belief states derived from individual observations. Stage I belief state is the likelihood of the system being in a certain state based solely on the current observation, without considering the influence of previous or future observations. The DBU model directly estimates these forward-state probabilities using Stage I belief. These probabilities are used to construct a likelihood function to train the model. By enabling the direct estimation of forward-state probabilities, the DBU model effectively captures the intricate transition dynamics of systems with interdependent chains.

3 - Degradation Control and Maintenance via Reinforcement Learning

Ying Fu, University of Wisconsin-Madison, Madison, WI, United States

Many industrial systems, such as manufacturing and energy facilities, consist of a fleet of units with redundancy that work together to meet production goals. As these units degrade over time, they require maintenance to keep the system operational. However, maintenance takes time and is often constrained by limited resources. During maintenance, the remaining units must take on additional workload to maintain overall productivity. Since degradation typically depends on workload, there is an opportunity to reduce maintenance costs and prevent failures by strategically distributing the operational workload across the fleet. For example, when maintenance capacity is fully utilized, assigning less workload to units nearing failure can slow their degradation and extend their lifespan. This study proposes a reinforcement

learning (RL) approach to jointly optimize workload allocation and maintenance scheduling. A case study using Raspberry Pi devices demonstrates the effectiveness of the proposed method.

4 - Variance-Aware Risk-Sensitive Reinforcement Learning

Saunak Kumar Panda, University of Houston, Houston, TX, United States

We propose a variance-penalized reinforcement learning (RL) framework that incorporates empirical uncertainty estimates to improve the reliability and stability of learned policies. Unlike prior methods that rely on auxiliary critics to approximate second moments of returns, our approach directly penalizes variance using non-parametric, statistically principled techniques such as bootstrapping and random scaling. These methods allow for efficient online variance estimation without additional value networks, enabling lightweight and scalable risk-sensitive learning. We instantiate this framework in both tabular Q-learning and a policy-gradient actor-critic algorithm, introducing empirical variance penalties into standard updates without compromising convergence. Empirically, our approach consistently achieves more stable policy behavior in stochastic domains, such as the noisy puddle world environment. Across discrete and continuous settings, the empirical variants match or outperform prior variance-penalized baselines in terms of return stability while retaining competitive expected performance. Our results highlight the potential of embedding non-parametric uncertainty estimation into the risk-sensitive RL paradigm without increasing model complexity.

1 - Repair-Aware Redundancy Allocation: A Hybrid Simulation and Metaheuristic Approach

Berna Dengiz, Baskent University, Ankara, Turkey, Merve Uzun, Orhan Dengiz

The Redundancy Allocation Problem (RAP) is important for designing reliable systems. In this study, we aim to find the best design for a series-parallel system by considering more realistic conditions. Unlike traditional methods that assume failed components cannot be fixed, we consider repairable components with increasing failure and repair rates that change over time. This makes the system more efficient and reduces unnecessary cost and weight.

We use a Discrete Event Simulation (DES) model together with Monte Carlo (MC) Simulation to estimate the reliability of the system. To solve the RAP, we apply two metaheuristic algorithms: a steady state Genetic Algorithm (ssGA) and a Memetic Algorithm (MA). The MA improves the ssGA by adding a smart local search method that uses problem knowledge.

Our results show that when repairable components are included in the model, the system can be designed with fewer spare parts, less weight, and lower cost while still maintaining high reliability. The MA also finds better solutions than the ssGA in the same amount of computation time.

2 - Nonintrusive Device-Level Pattern Recognition and Power Consumption Prediction in Buildings Through Sequential Variational Autoencoders

Salih Salihoglu, University of Miami, Coral Gables, FL, United States, Ramin Moghaddass

The accurate prediction and disaggregation of energy consumption at the device level in residential and commercial buildings remain critical for effective energy management and demand response. This study introduces a novel framework for nonintrusive load monitoring (NILM) by leveraging a deep generative modeling approach using sequential variational autoencoders (VAEs). Our method reframes appliance-level power disaggregation and forecasting as a dynamic state-space modeling problem, addressing key challenges such as overlapping device usage patterns, temporal dependencies, and data sparsity. The proposed model captures both the stochastic nature and temporal evolution of device usage through an autoregressive latent variable architecture. We incorporate long-term dependencies and inter-device interactions into the latent space without requiring intrusive sensing or labeled training data. Evaluations using generated and publicly available datasets demonstrate the model's performance in power consumption prediction compared to conventional NILM techniques. This work represents a significant step toward scalable and interpretable solutions for smart grid applications and energy-efficient building management.

3 - A Hybrid Isolation Forest and LSTM Variational Autoencoder Approach for Phase I Statistical Process Control

Waldyn Martinez, Miami University, Oxford, OH, United States

Phase I statistical process control (SPC) primarily involves analyzing historical data to detect outliers, assess process stability, and establish robust control limits for future monitoring. Traditional SPC methods often assume independence and stationarity of observations—assumptions frequently violated in complex industrial processes with autocorrelated or multivariate data. To address these limitations, we propose a novel hybrid methodology integrating Isolation Forests (IF) with a Long Short-Term Memory Variational Autoencoder (LSTM-VAE). The LSTM-VAE leverages temporal dependencies inherent in sequential data, capturing complex nonlinear dynamics and refining the distributions of the latent space for potentially more robust anomaly detection through reconstruction error analysis. Subsequently, the Isolation Forest provides the anomaly detection capability by effectively isolating anomalies without strong assumptions about data distribution. This hybrid approach significantly enhances detection accuracy and robustness, particularly in processes exhibiting temporal autocorrelation or intricate multivariate relationships. We demonstrate the effectiveness and practical applicability of our proposed method using simulated and real-world industrial datasets, highlighting its superior performance in accurately identifying anomalies and setting appropriate Phase I control limits.

4 - Productivity Change Estimation Under Data Uncertainty: a Forest-Based Probabilistic Approach

Yu Zhao, Tokyo University of Science, Shinjuku-ku, Japan

This study introduces a novel method for estimating productivity change that explicitly accounts for uncertainty in input-output data through the Malmquist Productivity Index framework. By applying a forest-based clustering and sampling procedure, we capture the underlying probabilistic structure of observed decision-making units (DMUs). Clusters are formed through recursive partitioning guided by a Gaussian-based entropy function that maximizes information gain. This enables the estimation of empirical distributions of efficiency scores, from which we derive confidence intervals for the Malmquist Index and its components—namely, catch-up and frontier-shift effects. The proposed method is validated using both simulated and real-world datasets, demonstrating its effectiveness in productivity analysis under stochastic environments.

5 - Efficient Statistical Tests for Personalization Effects

Zhaoqi Li, Stanford University, Stanford, CA, United States, Emma Brunskill

Personalized decision rules can outperform a single "one-size-fits-all" action, but they are worth learning only when personalization truly improves outcomes. In data from many real-world settings, one treatment dominates all other actions, and gathering the covariates needed to personalize can be costly. In these cases, it is of interest to test whether it is worth spending the effort to learn a personalized best policy, or a "one-size-fit-all" action suffices. To determine when personalization is justified, we propose a semiparametrically efficient test for the existence of the personalization effect, defined as the gain of the optimal context-dependent policy over the single best overall action. Our procedure uses a three-fold cross-fitted AIPW estimator that exploits the overlap between personalized and non-personalized recommendations and attains the semiparametric efficiency bound. We also use a repeated-split procedure that tightens finite-sample performance. We conduct simulations to show that the type-I error is controlled even when policy learning is imperfect. Our approach achieves a lower Type-I error when there is no personalization effect and a high power when there is personalization effect compared to the baseline. We also run real data experiments from various domains, including Jester jokes, MOOC interventions, and Job Corps earnings, that show the versatility of our algorithm in different settings. Together, these results provide an efficient and data-driven answer to the question "Is

personalization worth it?" and offer a ready-to-use toolkit for experimental design and policy evaluation across domains where individualized decisions may or may not pay off.

6 - High-Dimensional Statistical Process Control via Manifold Learning and Fitting

Ismail Tas, The Pennsylvania State University, State College, PA, United States, Enrique del Castillo

In modern industrial settings, processes often generate high-dimensional, temporally correlated data, challenging traditional Statistical Process Control (SPC) techniques. To address these limitations, we propose two novel Phase II SPC frameworks that address the geometry of high dimensional data under a manifold assumption. The first approach fits a smooth manifold in the ambient space and monitors deviations using a distribution-free univariate control chart. The second approach embeds high-dimensional observations into a lower-dimensional space and performs monitoring there using a distribution-free control chart. Both methods provide a controllable in-control average run length and demonstrate strong fault detection performance. We validate our approaches on the Tennessee Eastman Process Simulator, demonstrating their effectiveness in scenarios where traditional methods fail.

7 - Control Charts for Queues with Vacations

George Mytalas, Athens University Economics Business, Hlioupoli, Greece, Dimitris Zissis

In queues with vacations, the system benefits from vacation time to perform minor work as maintenance. Different policies are applied such as "Multiple", "Single" or "MAV." A well-designed control policy has a relative influence on the waiting time of customers as well as the service quality (QoS) of the system. For queues controlling the duration of vacations, the expected number of customers in the system is an important characteristic. We develop control charts for monitoring the expected system size in the M/M/1 queueing system with exponential vacation durations. Two methods of system parameters estimation applied for different vacation policies for control limit calculations are provided. Finally, we present an application example for illustrative purposes.

Behavioral Operations Management

Chair: Michelle Kinch, Tuck School of Business at Dartmouth College, Hanover, NH, United States

1 - Learning on the GO: How Gig Workers Learn with Algorithmic Recommendations

Park Sinchaisri, University of California Berkeley, Berkeley, CA, United States

Gig platforms increasingly rely on AI recommendation systems to guide workers in choosing tasks, yet we know little about how these systems shape decision-making and skill development over time. This study examines how gig workers learn, how their reliance on AI evolves, and what design principles can help recommendation systems support both short-term efficiency and long-term growth. Using detailed data from a retail delivery platform, we find early benefits from following AI guidance, but also evidence that experienced workers perform best when developing their own strategies. These insights motivate the design of adaptive, learning-aware AI systems that align with worker development and improve decision-making in dynamic environments.

2 - Worker Reactions to (Fair) Algorithms

Clare Snyder, NYU Stern, New York, NY, United States, Samantha Keppler, Stephen Leider

Despite the growing emphasis on fair algorithm design in ML research, human decision-makers remain key mediators of algorithmic outcomes. When people can deviate from and disregard algorithms' advice, it is possible they will do so in a way that undermines fairness objectives—just as algorithm aversion causes people to deviate from algorithms in ways that undermine their accuracy. In this paper, we explore how human decision authorities, such as loan officers, interact with fair algorithms, with a view towards understanding how their behavior affects fairness and accuracy objectives. With an online experiment (N=476), we compare subjects' decision-making processes across four algorithm treatments: an accuracy-only algorithm, a fair algorithm with an aggressive-threshold policy, a fair algorithm with a conservative-threshold policy, or no algorithm at all. We find participants under-rely on all algorithms, but use the fair algorithms' advice at particularly low rates. More critically, subjects' particular deviations from the fair algorithms result in lower fairness—measured by equality of opportunity—than participants without any algorithm or the fair algorithms themselves. This study contributes to an understanding of the way human behavior interferes with the effectiveness of fair algorithms and offers potential implications for improving human-algorithm collaboration in practical settings.

3 - Multistage Monitoring

Yue Li, Beijing Jiaotong University, Beijing, China, People's Republic of, Shuaikun Hou, Meng Li, Chao Liang

This paper explores the impact of algorithmic surveillance on task performance in a multistage sales process. We partner with a leading automobile company in Asia that has implemented algorithmic surveillance in select stores to provide real-time performance feedback to its call agents. Using a difference-in-differences approach, we examine the impact of algorithmic surveillance on agents' task initiation and task completion behaviors. Our analysis reveals that the introduction of algorithmic surveillance significantly reduces lead time—the duration between the assignment of an outbound call task and the initiation of the call—during the task initiation stage, without compromising task completion. In fact, we observe an increase in the conversion rate—the percentage of contacted customers who visit the store—indicating improved performance in the task completion stage as well. Moreover, our study explores the broader implications of algorithmic surveillance on workplace fairness, focusing on how the composition of different employee groups influences its effects on task performance. Our analysis reveals that not only do different employee groups (based on dimensions of gender, tenure, and position) exhibit varying responses, but their performance also differs depending on the task complexity. Our work highlights the important role of algorithmic surveillance in improving task performance in multistage processes and provides valuable insights for the development of a more equitable work environment.

4 - Negative Effects of Positive Real-TIME Feedback from AI

Michelle Kinch, Tuck School of Business at Dartmouth College, Hanover, NH, United States

Companies often rely on standard work protocols to increase efficiency in service delivery, but worker compliance remains a persistent challenge. This study examines whether real-time feedback from artificial intelligence ("AI-RTF") improves script adherence, task completion times and job satisfaction in customer contact center settings, while also assessing how its psychological impact on workers affects outcomes.

5 - Explaining Inconsistent Predictions

Zezen He, Simon Business School, University of Rochester, Rochester, NY, United States, Yaron Shaposhnik

In various machine learning applications, such as wait time prediction for customers in service, the model is repeatedly queried for predictions over time. This often occurs in response to changes in the dynamic characteristics of the user or the environment. Due to randomness, in many environments, predictions may change in ways that could seem unexpected or unreasonable to the user. For instance, predictions might oscillate between higher and lower values over time, a phenomenon we refer to as *intertemporal inconsistency*. For example, it is not uncommon for a customer to receive a short initial predicted wait time that later turns out to be a longer delay.

Motivated by research in psychology on adverse reactions to inconsistent behavior, we introduce the notion of *intertemporal explanations*, a novel form of explanation for model predictions that specifically aims to inform the user about the reasons behind intertemporal inconsistencies. We extend this method and further introduce the notion of *differential explanations* as information provided to users of machine learning models that explains why a model assigns different predicted values to two observations.

1 - How the Market Prices AI: Separating Adoption from Intention

John Sudeep Teli, Georgia State University, Atlanta, GA, United States, Arun Rai, Yu-Kai Lin

Artificial intelligence (AI) is an increasingly important driver of firm valuation, yet how the market prices AI remains incompletely understood. While firms frequently emphasize AI to enhance innovation and efficiency, the complexity and uncertainty surrounding AI make it difficult to assess its value. In this study, we investigate how the market prices AI by using data from 10-K filings. We distinguish firms' engagement in AI along two dimensions: AI Emphasis Current (AIEC), which reflects the extent to which a firm currently integrates AI into its business model, and AI Emphasis Planned (AIEP), which captures the firm's stated future intentions to adopt AI. Our results show that AIEC significantly predicts future stock returns, whereas AIEP does not, suggesting that the market underprices realized AI adoption but discounts forward-looking AI plans. We also examine changes in AIEC and AIEP as proxies for increases in current and planned AI engagement. We find that the market has no reaction to increases in AIEC in the short term but has a negative reaction to increases in AIEP. This implies that while the market overlooks new developments in AI adoption initially, it remains skeptical of newly stated intentions to adopt AI, possibly due to perceived implementation risk. Our study contributes to the literature on the economic value and risks of AI by focusing how different forms of AI engagement are valued, and to the mispricing literature by showing how investor pricing of AI-related information deviates from standard pricing fundamentals.

2 - Probing Personality with AI: Evaluating LLMs as Interviewers in Automated Hiring Systems

Rachit Kamdar, University of Maryland, College Park, MD, United States, Balaji Padmanabhan, Siva Viswanathan

The automation of hiring processes is increasingly central to organizational strategies aimed at enhancing recruitment efficiency and reducing costs. While resume screening remains the most widely used automation tool in recruitment, organizations are increasingly exploring ways to automate the interview process to further enhance hiring efficiency and reduce costs. Large language models (LLMs) offer a promising avenue for automating complex interviews through human-like conversational capabilities. However, their effectiveness in accurately assessing job-relevant characteristics, particularly personality traits that are critical to job performance remains under explored. This study investigates the effectiveness of LLM-conducted dynamic interviews, contrasting confrontational and non-confrontational interviewing styles, with traditional static question-based interviews in predicting self-reported personality traits. Drawing on established interviewing theories, we develop a novel interview design framework and evaluate it through a randomized controlled trial. Our findings reveal that LLM-driven dynamic interviews yield higher predictive accuracy of personality traits compared to static formats. Notably, confrontational LLM interviewers demonstrate superior accuracy in detecting negative traits such as neuroticism and disagreeableness. These insights have significant implications for the design of automated recruitment systems, highlighting the trade-offs between interview style, automation, and the accuracy of candidate assessments.

3 - Bandit-Based Offer Reshaping for Unassigned Tasks in Crowdsourcing Platforms

Young Yoon, Walmart, Sunnyvale, CA, United States, Yu Wang, Ibrahim El Shar, Hengchao Wang, Thomas Stiefel, Sherry Lijie Wan, Mingang Fu, Samuel Eldersveld

A key challenge faced by task requesters on crowdsourcing platforms is determining how to reshape task offers when they remain unassigned. This problem is particularly prevalent across many delivery platforms, where demands are predetermined, and task requesters need to make the unassigned offers more attractive to ensure timely acceptance. For example, task requesters can add subtasks with different prices to make the task more appealing. While prior research has focused on the initial matching of tasks with workers, studies on reshaping task offers are sparse.

We propose a bandit-based offer reshaping mechanism that utilizes a reverse-Dutch auction method to gradually modify task offers, such as by incrementally adding subtasks. The rate of adjustment (i.e., reshaping pattern) is determined using a novel pattern algorithm with parameters optimized through a multi-objective multi-armed bandit (MOMAB) framework. Additionally, we present an end-to-end system that integrates batched offline learning with online inference.

There are two additional challenges to our problem. First, task requesters commonly aim to improve a success metric while maintaining a guardrail metric within defined bounds. The challenge arises from the need to adapt to dynamic priorities when guardrail metrics fall outside of the bounds. We address this by using lexicographically scalarized expected rewards to prioritize objectives. Second, estimating expected rewards for batched learning is challenging due to the limited number of unassigned tasks per batch. We propose a new confidence-based learning method that dynamically adjusts learning rates.

Through offline evaluation, we provide empirical evidence that our approach achieves a regret of $O(\log^2(T))$.

Recent Advances in Spatiotemporal Data Mining

Invited Session

Data Mining

Chair: Adam Meyers, University of Miami, Miami, FL, United States

1 - Hybrid Diffusion-Transformer Approach for Multivariate TIME Series Imputation**Ramiro Valdés, University of Miami, Miami, FL, United States, Adam Meyers**

Many real-world spatiotemporal data contain gaps when sensors fail or communication issues occur. Spatiotemporal imputation focuses on reconstructing missing values by leveraging patterns that repeat across both space and time. In recent years, deep learning approaches have emerged as powerful tools for spatiotemporal imputation, consistently outperforming traditional methods. Although recent work has improved performance, two persistent gaps remain: (i) diffusion-based methods model uncertainty well but are confined to local temporal contexts and fixed spatial graphs, and (ii) transformer-style architectures capture long-range dependencies yet handle missing-value uncertainty only heuristically. We propose a hybrid method that addresses the limitations of each individual approach, namely, the Hybrid Diffusion Transformer (HDT). The diffusion component treats each time series as a noisy signal that can be gradually reconstructed, giving the model a way to handle uncertainty and to learn to remove the noise step by step. The transformer component adds an attention mechanism, enabling the model to simultaneously learn spatial correlations and non-stationary temporal patterns. During inference, the reverse diffusion trajectory, guided by the transformer component, iteratively reconstructs missing values while producing confidence intervals. By integrating these parts in a single, end-to-end framework, our approach offers a robust and interpretable solution for multivariate time series imputation. We evaluate HDT on varied traffic and physiological datasets chosen to test long-range and spatiotemporal dependencies. Model validation covers a range of missing-value patterns and compares mean absolute error (MAE) and root mean square error (RMSE) against state-of-the-art baseline methods.

2 - A Statistical Model for Monitoring Convolution-Generated Spatio-Temporal Gaussian Processes**Yutong Zhang, Georgia Institute of Technology, Atlanta, GA, United States, Xiao Liu**

A large class of Gaussian spatio-temporal processes can be constructed through a sequence of convolution operations in time and space. For example, stochastic advection-diffusion processes with a Gaussian noise, heat equations with a random force driven by a Gaussian process, etc. For many of these processes, one is interested in monitoring the first-order time derivative which plays a critical role in change point detection of such processes. In this paper, we propose a statistical model that is effective in monitoring the first-order time derivative of convolution-generated Gaussian space-time processes. An infinite-dimensional stochastic differential equation (SDE) representation is firstly obtained. Then, a finite-dimensional approximation, based on the Gelerkin projection, is proposed to yield a computationally-efficient state-space representation. Numerical investigations are performed based on both a simulation dataset and a real dataset of the Aerosol Optical Depth during 2025 Los Angeles wildfires. Comparison studies show that the proposed approach provides significant advantages over existing approaches in monitoring convolution-generated space-time Gaussian processes.

3 - Topology-Aware Conformal Prediction for Stream Networks**Fangxin Wang, University of Illinois Chicago, Chicago, IL, United States**

Stream networks, a unique class of spatiotemporal graphs, exhibit complex directional flow constraints and evolving dependencies, making uncertainty quantification a critical yet challenging task. Traditional conformal prediction methods struggle in this setting due to the need for joint predictions across multiple interdependent locations and the intricate spatio-temporal dependencies inherent in stream networks. Existing approaches either neglect dependencies, leading to overly conservative predictions, or rely solely on data-driven estimations, failing to capture the rich topological structure of the network. To address these challenges, we propose Spatio-Temporal Adaptive Conformal Inference (STACI), a novel framework that integrates network topology and temporal dynamics into the conformal prediction framework. STACI introduces a topology-aware nonconformity score that respects directional flow constraints and dynamically adjusts prediction sets to account for temporal distributional shifts. We provide theoretical guarantees on the validity of our approach and demonstrate its superior performance on both synthetic and real-world datasets. Our results show that STACI effectively balances prediction efficiency and coverage, outperforming existing conformal prediction methods for stream networks.

4 - Geometry-Aware Active Learning of Spatiotemporal Dynamic Systems**Xizhuo Zhang, University of Tennessee, Knoxville, TN, United States**

Rapid developments in advanced sensing and imaging have significantly enhanced information visibility, opening opportunities for predictive modeling of complex dynamic systems. However, sensing signals acquired from such complex systems are often distributed across 3D geometries and rapidly evolving over time, posing significant challenges in spatiotemporal predictive modeling. This paper proposes a geometry-aware active learning framework for modeling spatiotemporal dynamic systems. Specifically, we propose a geometry-aware spatiotemporal Gaussian Process (G-ST-GP) to effectively integrate the temporal correlations and geometric manifold features for reliable prediction of high-dimensional dynamic behaviors. In addition, we develop an adaptive active learning strategy to strategically identify informative spatial locations for data collection and further maximize the prediction accuracy. This strategy achieves the adaptive trade-off between the prediction uncertainty in the G-ST-GP model and the space-filling design guided by the geodesic distance across the 3D geometry. We implement the proposed framework to model the spatiotemporal electrodynamics in a 3D heart geometry. Numerical experiments show that our framework outperforms traditional methods lacking the mechanism of geometric information incorporation or effective data collection.

5 - Multi-Graph Structure Learning for Multivariate TIME Series Anomaly Detection**Jaeyeon Lee, KAIST, Daejeon, Korea, Republic of, Heeyoung Kim**

Industrial processes often generate complex, interdependent time-series data from multiple sensors across multiple stages, forming complex dependencies among variables and process stages. Effective monitoring and timely anomaly detection of these time series through multivariate time series anomaly detection (MTAD) are crucial for preventing failures and maintaining system reliability. Graph neural networks (GNNs) have advanced MTAD by leveraging data-driven graphs to model complex dependencies among variables, effectively capturing relational structures within multivariate time series to enhance anomaly detection performance. We propose a novel GNN-based MTAD method that constructs and integrates multiple complementary graphs to better represent inter-variable relationships. Comprehensive experiments on two real-world, multi-stage industrial datasets demonstrate that our method outperforms state-of-the-art baselines in anomaly detection performance.

6 - Adaptive Sampling for Concept Drift Detection**Junghye Pyeon, Georgia Institute of Technology, Alpharetta, GA, United States, Davide Cacciarelli, Kamran Paynabar**

Concept drift and label scarcity are two critical challenges limiting the robustness of predictive models in dynamic industrial environments. Existing drift detection methods often assume global shifts and rely on dense supervision, making them ill-suited for regression tasks with local drifts and limited labels. This paper proposes an adaptive sampling framework that combines residual-based exploration and exploitation with EWMA monitoring to efficiently detect local concept drift under label constraints. Empirical results on synthetic benchmarks and a real-world electricity market case study demonstrate superior performance in label efficiency and drift detection accuracy.

AI-Driven Methods for Clinical Decision Support

Invited Session

Data Mining

Chair: Vasiliki Stoumpou, Massachusetts Institute of Technology, Cambridge, MA, 02139, United States

1 - Holistic AI in Medicine: Improving Performance and Explainability**George Margaritis, Massachusetts Institute of Technology (MIT), Cambridge, MA, United States, Periklis Petridis, Vasiliki Stoumpou, Dimitris Bertsimas**

Deployment of Artificial Intelligence (AI) solutions in real-world clinical settings faces critical challenges in ensuring both prediction accuracy and explainability. Extracting useful and interpretable features from the overwhelming volumes of patient data remains a largely unsolved problem. Existing approaches typically rely on averaging embeddings over multiple time instances and data elements (e.g. clinical notes), often degrading predictive performance and obscuring clinical meaning. We

present xHAIM (Explainable Holistic Artificial Intelligence in Medicine), a novel framework that attempts to address these limitations through a generalizable 4-step approach. xHAIM automatically identifies task-relevant patient data across multiple modalities, generates comprehensive task-specific and patient-specific summaries, uses these summaries to enhance predictive performance, and provides clinically relevant explanations by combining predictions with existing medical knowledge. Our evaluation using the MIMIC-IV dataset demonstrates significant performance improvements over the baseline, with AUC increases that reach as much as 11% in chest pathology prediction tasks. We also show that in the majority of cases, the system is able to correctly justify model predictions by citing relevant sections of the patient's Electronic Health Record, thus paving the way for an accurate and interpretable clinical decision support system.

2 - Automated Differential Diagnosis: A Pomdp Framework for Optimal Diagnostic Test Selection in the Emergency Department

Karl Zhu, Massachusetts Institute of Technology, Cambridge, MA, United States, Yubing Cui, Matthew Peroni, Vasiliki Stoumpou, Cindy Wang, Dimitris Bertsimas

We present a POMDP model for automating diagnostic test selection in the Emergency Department (ED), where clinicians must quickly and accurately perform differential diagnosis. Using real electronic health records from Hartford HealthCare—one of the largest hospital systems in Connecticut—we initialize a belief over 25 Major Diagnostic Categories using an XGBoost model trained on demographics, vitals, and chief complaints. This belief is refined through the results of diagnostic lab and imaging tests (e.g., metabolic panels, urinalysis, ultrasound). The objective minimizes both test costs and final diagnostic uncertainty, measured by entropy. Solving the POMDP exactly for each patient and simulating synthetic test outcomes, we show that the optimal policy significantly improves diagnostic accuracy—demonstrating its potential as a clinical decision support tool.

3 - Road 3: Mitigating Observed and Unobserved Confounding in Observational Data

Vasiliki Stoumpou, Massachusetts Institute of Technology, Cambridge, MA, United States, Georgios Antonios Margonis, Dimitris Bertsimas

Randomized clinical trials are widely regarded as the gold standard for assessing treatment effects in medical settings. In contrast, observational data lack randomization, leading to imbalances between treatment arms due to confounding factors. While many causal inference methods attempt to adjust for observed confounding, they often operate under the assumption that unobserved confounding is absent. In this work, we challenge that assumption by proposing a novel method to estimate the portion of patient outcomes that cannot be explained by observed variables—effectively introducing a proxy for unobserved confounding. We then leverage this proxy, alongside the known medical covariates, to construct a balanced cohort that better emulates a randomized trial population. We evaluate our approach across four datasets—two purely observational and two randomized trials with synthetically introduced confounding—and show that it consistently outperforms standard methods that account for observed confounding only. Our method offers a promising direction for enabling personalized treatment decisions in contexts where treatment effects are not known a priori.

4 - Detection, Localization and Progression Prediction of Subdural Hematoma

Rohan Kumar, Massachusetts Institute of Technology, Cambridge, MA, United States

A subdural hematoma is a type of intracranial bleed that occurs on the surface of the brain. Aging, trauma in the head, use of anticoagulants and alcohol, and coagulopathies have been linked to the occurrence of subdural hemorrhages. Subacute/chronic subdural hematoma is expected to emerge as a predominant neurosurgical concern in the United States by 2030, primarily attributed to increasing life expectancy and the expanding utilization of antiplatelet and anticoagulation medications. The present work evaluates the efficacy of machine learning (ML) approaches used to predict the existence, localization, and progression of chronic subdural hematoma. We perform these tasks using demographics, labs, medications and image data and utilizing deep learning architectures to perform classification and segmentation of the images, to detect the area of the hematoma. Then, we employ the segmented scans and hematoma existence prediction results to understand the prognosis of the condition with or without clinical intervention. Our aim is to provide clinicians with a robust AI tool that provides them with information regarding the probability of the existence, location, and progression of a hematoma.

Innovation in Services

Invited Session

Technology, Innovation Management and Entrepreneurship

Chair: Abhishek Deshmane, Georgia Institute of Technology, Atlanta, GA, United States

1 - New Technology Adoption and Peer Effects Among Service Workers: Evidence from Aadhaar Enabled Payment System

Deepanshi Bhardwaj, University College London, London, United Kingdom, Bilal Gokpinar, Ashwini Chhatre

Given the increasing pace of new technology introductions and associated adoption challenges experienced by service workers, our study investigates whether and to what extent peers affect service workers' performance during new technology adoption. Using a granular transaction level dataset of bank-service agents in India, and examining the introduction of a new digital payment system (Aadhaar Enabled Payment System – AePS), we find that at the onset of AePS, agents with peers exhibit a 6% lower failure rate of transactions in comparison to agents with no peers. We also find that more experienced peers provide stronger peer effects than less experienced peers. In addition, competition hinders peer effects in that having peers who compete for the same customer pool or peers who are competitive based on their job nature (full-time in comparison to part-time) significantly weakens benefits gained from having peers. Our study provides novel and detailed empirical evidence of peer effects at the onset of a new technology introduction. Our findings contribute to the literature on innovation and technology management by extending the scope of peer effects from day-to-day operations to the critical phase of new technology adoption, and offer important insights into organization and management of service workers during this critical period.

2 - Small and Medium Enterprises in Open Innovation

Gaoyu Xie, George Washington University, Washington, DC, United States, Pascale Crama, Janne Kettunen

We develop a game-theoretic model to examine the innovation strategies of small and medium-sized enterprises (SMEs), focusing on two key frictions that differentiate them from large firms: risk aversion and the cost of capital. These frictions contribute to both innovation and launch inefficiencies, ultimately suppressing SMEs' innovativeness. Our model explores whether establishing an open innovation (OI) ecosystem—where SMEs collaborate with large supplier firms—can enhance innovation outcomes. We find that involving suppliers in the innovation process reduces innovation inefficiency, although launch inefficiency may persist when fixed costs are low. Participation in OI is particularly beneficial under high market uncertainty but provides limited value when both fixed costs and technical uncertainty are high.

3 - Double-Edged Sword: Impact of AI on Production of Knowledge

Hyunwoo Park, Seoul National University, Seoul, Korea, Republic of, Seokbeom Kwon, Hyun Ju Jung

This study examines how AI integration reshapes research performance and collaborative dynamics among scientists facing potential displacement by AI tools. Using DeepMind AlphaFold's 2018 entry into the CASP13 protein structure prediction competition as an exogenous shock, we employ a difference-in-differences design on scientists' publication and citation panel data. Our research investigates differential impacts across career stages, examining how senior and junior scientists' productivity and impact metrics respond to AI introduction. Through co-authorship network analysis, we explore how scientists reposition themselves within collaborative structures following AI disruption. We also analyze whether strategic AI adoption can mitigate potential adverse effects on research impact. This work contributes to our understanding of AI's multifaceted influence on scientific communities and knowledge production institutions. Our findings provide insights into career-stage-dependent effects of AI augmentation on scientific practice, informing both policy and individual career strategies in an increasingly AI-influenced research landscape.

1 - A Hyperheuristic Hybridized with Exact Optimization for the Berth Allocation and Scheduling Decision Problem

Bokang Li, Florida A&M University-Florida State University, Tallahassee, FL, United States, Fatemeh Shekoochi, Payam Afkhami, Maxim Dulebenets

Berth allocation and scheduling at marine container terminals holds critical significance for optimizing port operations and ensuring efficient maritime logistics, yet it is exceptionally challenging due to its operational complexity and practical constraints. This study presents a mixed-integer linear programming model for the dynamic discrete berth allocation and scheduling problem with the objective to minimize the total turnaround cost and develop an efficient service schedule for each incoming vessel with a feasible service order and berthing position. A novel Hyperheuristic Hybridized with Exact Optimization (HHEO) is developed to explicitly solve the challenging decision problem studied herein. The HHEO algorithm is designed to dynamically select and apply different genetic operators based on their actual performance. Furthermore, intelligent exact optimization procedures specific to the domain of berth allocation and scheduling are periodically employed within the HHEO framework to improve solution quality and facilitate search for high-quality solutions. Detailed computational experiments are carried out to prove the superiority of the HHEO algorithm against solution methods inspired by exact optimization along with some well-known metaheuristic algorithms, demonstrating its efficiency and applicability for real-life berth planning at marine container terminals. Moreover, the experiments clearly demonstrate that incorporating a hyperheuristic framework along with problem-specific hybridization methods is critical for improving the exploratory and exploitative capabilities of the developed HHEO algorithm. Last but not least, valuable practical insights are uncovered through the proposed approach, offering reliable solutions that can support effective port management under different scenarios of berthing availability, vessel arrival intensity, and delayed vessel departure penalties.

2 - Multiphysics-Informed Neural Network for Simulating Electromechanics of Atrial Fibrillation

Weixuan Dong, The University of Oklahoma, Norman, OK, United States, Yifu Li, Stavros Stavrakis, Rui Zhu

Realistic patient-specific simulations are crucial for treating atrial fibrillation (AF), a cardiac arrhythmia driven by multi-physical processes. Current research mainly focuses on single-physics simulations due to computational complexity. To address this, we develop a Multiphysics-informed neural network that captures AF's complex dynamics, bringing simulations closer to real human hearts.

3 - AI Impact on Digital Marketing: Detecting Behavioral Changes

Melody Han, St. John's School, Houston, TX, United States, Zijun Zhan, Tony Cui

Using Fiverr data, we examined the impact of AI adoption on client retention and service demand using regression and CUSUM methods. Our findings reveal significant behavioral shifts triggered by AI, offering valuable insights into platform strategy, customer lifecycle management, and the timing of technology-induced disruptions in digital marketplaces. These insights can guide managers in optimizing service offerings, enhancing customer engagement, and maintaining competitive advantage in a rapidly evolving market.

4 - Multi-Task Learning-Based Shared Encoder Framework for Robust Anomaly Detection

wonjae Kim, Department of Industrial and Management Engineering, Incheon National University, Incheon, Korea, Republic of, Jaehong Yu

Recently, the importance of anomaly detection for early detection of equipment abnormalities in industrial sites has been highlighted. However, existing anomaly detection methods do not reflect the distribution differences between normal data collected in various operating environments, resulting in a problem of reduced anomaly detection performance. In this study, we propose a methodology to robustly detect anomalies in various operating environments by converting signal data into spectrograms, forming a cluster structure of normal data in latent space using deep clustering-based learning, and calculating a novelty score based on this.

5 - Integrated Multi-Objective Optimization and Spatial Analysis for the Site Selection of Levee Crossing Facilities

Tsun-Yuan Ku, Department of Geomatics, National Cheng Kung University, Tainan, Taiwan, Febrian Fitryanik Susanta, PEI-FEN KUO, Chung-Wei Shen, Ching-Jui Lai, Nan-You Chen

In many large riverside cities, levee systems serve dual roles in flood control and urban recreation by enabling parks and jogging paths along and beyond embankments. However, pedestrian access to these off-levee spaces often depends on crossing infrastructure, such as stairs and ramps, originally intended for maintenance rather than public use. These facilities often lack accessibility compliance, posing barriers for elderly and mobility-impaired users. Moreover, the spatial distribution of these crossings is frequently uneven and poorly integrated with pedestrian networks.

This study focuses on the Sanchong and Luzhou districts of New Taipei City, Taiwan, an area of 560,000 residents within 23 km², enclosed by a circular embankment over 16 km long and currently served by 103 levee-crossing facilities. A smart site selection framework is proposed to prioritize facility upgrades under budget constraints, aiming to improve walkability and spatial equity. The model addresses three objectives: (1) maximizing accessibility by meeting pedestrian demand, (2) minimizing sidewalk retrofit costs in high-demand areas, and (3) minimizing reconstruction costs of crossing facilities. A spatial dispersion mechanism discourages clustering and improves overall network efficiency.

To address the complex, multi-objective nature of the levee crossing site selection problem, we adopt two optimization approaches: the Non-dominated Sorting Genetic Algorithm III (NSGA-III) and a Quadratic Unconstrained Binary Optimization (QUBO) formulation. Both methods generate a well-distributed Pareto front while ensuring solution diversity. The solution sets are compared in terms of quality, spatial feasibility, and trade-off structure, providing effective solutions to this site facility location problem.

6 - Overconfident Pitches, Vulnerable Investors: the Role of Financial Literacy in Crowdfunding and the Need for Consumer Protection Nudges

Andres Riofrio-Lara, Ivey Business School, London, ON, Canada, Elena Fumagalli, Giovanni Visentin, Fabiana Penas

Crowdfunding democratizes access to capital for entrepreneurs, but it also exposes consumers to heightened financial risk. Platforms like Kickstarter face persistent concerns regarding fraud and non-delivery, with nearly 18% of the funds raised estimated to stem from deception campaigns. We investigate how founder overconfidence, manifested as overestimation, overplacement and overprecision, affects consumer pledging behavior.

We develop a linguistic manipulation of a crowdfunding pitch and examine its interaction with consumers' financial literacy. In our initial experiment (n = 200), participants were randomly assigned to view either a neutral or an overconfident pitch for a 3D printer project, then selected investment alternatives mirroring Kickstarter's structure. Financial literacy and risk preferences were subsequently assessed using validated scales. Results show that exposure to an overconfident pitch significantly increased pledging among financially illiterate consumers, while financially literate participants exhibited greater skepticism and lower investment levels. These effects remained robust across multiple model specifications, even after controlling for investor overconfidence, domain knowledge, and prior crowdfunding experience. Additionally, we identify an interaction between risk preferences and the treatment that also shapes the investment decision.

These findings highlight the phenomenon of overconfidence contagion in consumer decision making, underlining a mechanism by which cognitive biases can exacerbate financial vulnerability. Our work contributes to the literature on behavioral finance, fintech consumer protection and decision hygiene. Future research will explore the role of overconfidence cues and the potential of decision hygiene nudges to mitigate cognitive bias and enhance investor safeguards in crowdfunding environments.

7 - An Integrated Web Tool for Nutrient Optimization and Watershed Model Selection in Harmful Algal Bloom Mitigation

Ashim Khanal, University of South Florida, Tampa, FL, United States, Hadi Charkhgard, Qiong Zhang, Mauricio E. Arias, David Kaplan

Harmful algal blooms (HABs) are intensifying in frequency and severity, posing significant threats to public health, aquatic ecosystems, and the economy. Excessive nutrient loading—primarily phosphorus (P) and nitrogen (N)—is a major driver of HABs, often stemming from agricultural and urban runoff. While Best Management Practices (BMPs) offer a promising solution to reduce nutrient loads, selecting the most effective BMPs and their optimal placement within a watershed remains a complex challenge.

This poster presents a user-friendly, web-based decision support tool that integrates watershed modeling and optimization to aid in HAB mitigation. The tool features a model selector that helps users identify the most suitable hydrological model—such as WAM or SWAT—based on watershed characteristics. It includes backend automation that transforms model outputs into the format required by AquaNutriOpt, a surrogate-based optimization framework that identifies cost-effective BMP strategies under uncertainty.

The web tool allows users to perform single or bi-objective optimization for P and N across multiple future scenarios. It includes interactive visualization, guided tutorials, and downloadable documentation to enhance accessibility for diverse stakeholders. We have demonstrated the Optimization engine's effectiveness through a case study with Watershed Assessment Model (WAM) as primary hydrological model and watersheds of Lake Okeechobee as study area. This integrated platform empowers water managers, researchers, and policymakers with a streamlined, science-based approach for controlling nutrient pollution and mitigating HABs.

8 - Estimating Potential Future Profitability of Battery Storage Using Electricity Market Price Decomposition

Julia Frohmann, Stanford University, Stanford, CA, United States

Decarbonizing the U.S. electricity grid requires large-scale deployment of battery energy storage systems (BESS), spanning durations from 4 to 100+ hours. However, the pace of deployment is constrained by uncertain project profitability, particularly as revenue opportunities decline due to increasing wholesale market saturation (a trend already impacting ancillary services in CAISO and ERCOT). To address this, we constructed a future electricity price generator to assess potential scenarios of storage revenues under evolving energy and ancillary services market conditions.

Our approach employs Discrete Fourier Transform to decompose historical data and generate potential future price time series. The generator allows user-defined modulation of duck curve depth, underlying trends, and stochastic peak events, capturing typical diurnal and seasonal patterns well. Coupled with the battery dispatch optimization model DER-VET, we simulate BESS operations for 41 CAISO nodes, 9 future scenarios, and storage durations from 1 to 12 hours.

Revenue optimization results from synthetic price data are 6.7% lower than real price results, yielding a conservative estimate potential revenues. When comparing different generated potential future scenarios, we find that revenues can drop by 23.3% if both the energy arbitrage potential and the ancillary services prices decrease compared to 2023 revenue, making these projects much less attractive to developers. Also, BESS beyond 6h duration are uneconomical in the current market. These findings underscore the urgent need to develop storage-adapted market and contract mechanisms to compensate long(er) duration storage providers and enable cost-optimal buildout.

9 - Learning-Based Cpu Burst Prediction for Efficient Scheduling in Operating Systems

Md Nazmus Shakib, University of Alabama in Huntsville, Huntsville, AL, United States, Rahul Bhadani

In high-performance computing environments, scheduling decisions rely heavily on estimating how long a process will occupy the CPU. Conventional estimation techniques often fall short under varying workloads, limiting their effectiveness in modern, multi-user systems. This work introduces a data-driven framework that uses machine learning to predict process burst times using only features known at submission time. We evaluate several machine learning models, including decision trees, random forests, and multi-layer perceptrons, using real-world scheduling traces. Among them, the decision tree model offers the best trade-off between accuracy and speed. It achieves a mean absolute error (MAE) of 3514.09 and relative absolute error (RAE) of 12.64%, which is significantly lower than the exponential averaging baseline (MAE: 14833 ms, RAE: 53.34%), while keeping inference time per sample around 0.0033 milliseconds, making it suitable for real-time scheduling. Compared to exponential averaging, the learning-based models provide improved accuracy across a variety of workload conditions. The early availability of accurate predictions allows schedulers to make better decisions without introducing significant delay. This helps reduce wait times and improves overall CPU utilization. The study also includes model tuning and performance validation using 95% confidence intervals to ensure the results are consistent and reliable. By introducing a fast and accurate prediction method, this work supports efficient CPU scheduling strategies that respond well to real-world system demands.

10 - Decomposition-Based Framework for Optimizing Transit Stop and Route Placement to Enhance Accessibility in Transit Deserts

Md Gulam Kibria, Georgia Institute of Technology, Atlanta, GA, United States, Srinivas Peeta

Public transit offers a more sustainable and affordable alternative to personal vehicle travel, yet its adoption remains limited in many urban areas due to insufficient service coverage and poor connectivity. These challenges are particularly severe in transit deserts, where residents lack reasonable access to reliable transit options. This study addresses these challenges by developing an optimization framework to strategically expand transit stop locations and route connections with the goal of improving access to essential destinations such as jobs, education, healthcare, and grocery stores. It formulates a bi-objective optimization problem that identifies the optimal spatial configuration of transit stops and the connecting network of links. The two objectives are: (i) to maximize accessibility to key destinations across the service region, and (ii) to minimize the infrastructural and operational costs associated with new stop and link placements. To ensure computational efficiency for mid-sized and large-sized networks, a decomposition-based solution algorithm is proposed that iteratively solves reduced subproblems for stop selection and route connectivity while maintaining solution feasibility. Numerical experiments are conducted on both a synthetic grid network and a real-world network representing the City of Peachtree Corners, GA. Results show that the proposed approach significantly improves accessibility in transit deserts and lowers the Gini coefficient of accessibility distribution. The framework provides practical insights that can inform a range of stakeholders involved in planning, funding, and operating transit systems.

11 - Nonlinear Spatio-Temporal Run-to-Run Control: Leveraging Diffusion Models for Disturbance Management

Zihan Zhang, Georgia Institute of Technology, Atlanta, GA, United States, Lingchao Mao, Jianjun Shi, Kamran Paynabar

Run-to-run (R2R) control is widely used in advanced manufacturing processes. Conventional R2R control methods often assume that system disturbances exhibit linear structures or low-rank approximations in high-dimensional data, such as images or videos. While these assumptions facilitate implementation, they limit the effectiveness of R2R control in managing sophisticated manufacturing processes with intricate nonlinear disturbances. To address these challenges, we propose a novel nonlinear spatio-temporal R2R control framework that estimates system disturbances using a diffusion model and applies control actions to compensate for them. The proposed approach integrates an offline modeling phase to capture disturbance dynamics and an online control phase that dynamically adjusts actions to minimize deviations from the target system response, ensuring system stability and precision. Unlike conventional deterministic control strategies, the proposed method explicitly quantifies uncertainty, enabling more robust and informed decision-making. The effectiveness of this method is validated through simulation studies and a case study, demonstrating its adaptability in complex, high-dimensional environments.

12 - The Madness of Multiple Entries in March Madness

Jeff Sylvestre-Decary, University of Connecticut, Storrs, CT, United States, David Bergman, Carlos Cardonha, Jason Imbrogno, Andrea Lodi

This paper investigates the effectiveness of maximizing the expected value of the best performing entry in multi-entry betting pools for single-elimination tournaments, with a particular focus on March Madness. In such betting pools, participants select winners for each game, and their score is a weighted sum of the correct selections. Due to the top heavy payout structures in these pools, we study whether maximizing the expected score of the highest-scoring entry, which has been successfully adopted in the sports betting literature, is a suitable modeling approach for March Madness betting pools. Unlike traditional methods that require modeling how other participants make their selections—an especially challenging task given that March Madness only occurs annually—this approach only requires win probability estimates for teams as input, and inherently provides a diversified position across multiple entries. We present an exact dynamic programming approach for calculating the expected maximum score of any fixed set of entries. Additionally, we explore the structural properties of this approach to develop several solution techniques. Using insights from one of our

algorithms, we design a simple yet effective heuristic which delivers high-quality results when tested against high-roller bettors in a real world March Madness betting pool. In particular, our results demonstrate that the best 100 entry solution identified by our approach had a 2.45% likelihood of winning a \$1 million prize and an expected profit of \$14,502.43 in a real-world betting pool, showing that the proposed heuristic is competitive even against the best professional bettors.

13 - Optimizing Pallet Utilization to Reduce Curing Costs in Precast Concrete Manufacturing

Anik Mazumder, Louisiana State University, Baton Rouge, LA, United States, Bhaba Sarker

Efficient curing of precast concrete (PC) components is vital for ensuring consistent material strength where meeting delivery deadlines and controlling production costs should also be considered. This study develops an optimization framework to find an optimal layout configuration to arrange PC components on pallets and to minimize batch or pallet cycles during the curing process. An mixed integer linear programming model has been formulated that assigns components to pallets under area and demand constraints, aiming to reduce the total number of curing batches and associated energy and labor costs. To address rising computational times as component sizes and demand volumes grow, a custom branch and bound heuristic is proposed to generate high-quality layouts rapidly. Computational experiments using industrial case study show that optimized curing can decrease cost by up to 20 % and cut CPU time by 30 % compared to baseline configurations. Sensitivity analysis highlights that beyond a certain packing density, additional consolidation yields diminishing returns, guiding practical batch-size decisions. By ensuring uniform curing conditions and reducing batch cycles, the approach not only lowers immediate production expenses but also contributes to long-term sustainability through reduced maintenance and repair needs. Future work will focus on identifying key variables for faster layout generation and integrating the model with real-time production scheduling systems.

14 - Llm-Enhanced, Data-Driven Personalized and Equitable Anesthesiologist Scheduling Under Uncertainty: a Joint Prediction and Optimization Approach

Anjali Jha, University of Maryland Baltimore County, Baltimore, MD, United States, Maxim Eckmann, Muhammad Ali Yousuf, Kai Sun

Anesthesiologist scheduling remains a challenge due to limited clinical resources and fluctuating demands. This complexity is especially acute in large academic anesthesiology departments as physicians balance responsibilities across multiple clinical sites with conflicting priorities. Further, scheduling must account for individuals' clinical and lifestyle preferences to ensure job satisfaction and well-being.

Traditional approaches, often based on statistical or rule-based optimization models, e.g., stochastic optimization or mixed-integer programming (MIP), rely on structured data and explicit domain knowledge. However, these methods often overlook unstructured information, e.g., free-text notes from routinely administered clinician well-being surveys and scheduling platforms. These notes may reveal implicit constraints (post-call recovery needs, early departures for family obligations) and underutilized clinical resources (a physician's willingness to work additional hours to address emergent needs).

Neglecting such information can lead to misaligned schedules, increased burnout, overlooked staffing flexibility, and suboptimal utilization of available resources. To bridge this gap, we propose a joint prediction and optimization framework that integrates MIP with LLM-based clinician preferences. The LLMs extract actionable preferences and implicit constraints from unstructured survey and scheduling notes, which then inform a multi-objective optimization program considering schedule consistency, fair workload distribution, and contractual full-time equivalent allocations.

To enhance reliability, a validation layer that treats LLM outputs as intermediate signals to reduce hallucination risks is implemented to ensure operational robustness. The proposed approach combines the interpretive strength of LLMs with the rigor of mathematical optimization to deliver a practical, data-driven solution that promotes clinician satisfaction and improves operational efficiency in complex healthcare settings.

15 - Decision Support Using a Bayesian Digital Twin for Personalized Medical Decision Making

Fangzhou Xie, Boston University, Boston, MA, United States, Yangyuechen Zhao

A real-time decision aid shows the personalized benefits and side effect probabilities for treatment options. It utilizes a digital twin virtual patient representation that integrates electronic health records and patient reported outcomes. A Bayesian framework (prediction model prior) continuously updates information (prediction model posterior) or alerts clinicians of inconsistencies.

16 - Decision-Aware Predictions for Right-Hand Side Parameters in Linear Programs

Jackson Forner, Southern Methodist University, Dallas, TX, United States, Miju Ahn, Harsha Gangammanavar

In this talk, we consider the following predict-then-optimize problem: (1) predict uncertain right-hand side parameters of linear programs (LPs) using associated context/feature data, and (2) solve the resulting deterministic LP. A natural issue that arises when making such predictions is that the resulting optimal solution (if one exists) may be infeasible under the true realization of the right-hand side parameters. With this in mind, we propose a class of *decision-aware prediction models* that learns the relationship between context and right-hand side parameters in a way that yields high feasibility of predicted solutions. These models contrast decision-unaware prediction models, such as linear or random forests regression models, which treat right-hand side parameters simply as target values, i.e., not as parameters of an optimization problem. To compare these two classes of models, we use a synthetic data experiment as well as two real-life network LP problems: a bioenergy supply chain problem with uncertain biofuel demand, and a beer distribution problem with uncertain consumer demand. We show that our proposed decision-aware models achieve higher out-of-sample feasibility when compared to the decision-unaware regression models, with only a mild loss in solution quality as measured by a gap in optimal objective function value.

17 - A Nash Equilibrium Model for Reverse Logistics for Electric Vehicle Batteries

MD Mohiuddin, University of Louisville, Louisville, KY, United States, Lihui Bai

The rapid growth of the electric vehicle (EV) market puts strain on the raw material supply for new EV batteries (EVBs). Recovering materials from end-of-life (EoL) EVBs offer a promising secondary source. This study develops a novel Nash equilibrium model to design a reverse logistics system for EVBs, consisting of three players, i.e., end-of-life EVB collectors, recyclers, and manufacturers. The equilibrium model describes each player's own profit maximization behavior while linked to one another through market-clearing conditions. We show the existence and uniqueness of the equilibrium solution. We propose a modified projection method for solving the Nash equilibrium as a variational inequality. We report the numerical results for a case study involving the EVB manufacturing system in Kentucky. Future work will extend the current model to study various trade, government incentives and environmental policies.

Monday Poster Session

Poster Session

1 - Project Portfolio Selection at a Brazilian Investment Bank: a Multicriteria Decision-Making Approach Using the Promethee V Method

Andréia Kaori Io Imai Gomes, Aeronautics Institute of Technology, São José dos Campos, Brazil, Arsênio Gomes Neto, Jonas Almeida

The selection of project portfolios in contexts with limited availability of specialists is a recurring and challenging activity within organizations. In this context, this study presents a multicriteria model to support the selection of project portfolios in a Brazilian investment bank. Accordingly, the modeling was conducted using a structured approach consisting of 12 steps, encompassing all stages from stakeholder definition to the final decision recommendation. To this end, the PROMETHEE V method was chosen for being aligned with the non-compensatory rationality of the decision-maker and for allowing explicit consideration of constraints, in this case, the maximum number of specialists available to execute the projects. Following this, seven criteria were defined for the application of the model: "Criticality," "Strategic Area," "Time in Backlog," "Estimated Duration," "Technical Capacity," "Operational Efficiency," and "Priority." In this context, the consequence matrix was composed of 10 alternatives, corresponding to the projects eligible for the portfolio. As a result, an optimal portfolio (P8) was identified, consisting of eight projects and maximizing the adapted net outranking flow. The robustness of the solution was assessed through a sensitivity analysis with $\pm 10\%$ variations in the criteria weights and in the values for the "Estimated Duration" criterion. Based on these results, we observed that portfolio P8 was reproduced in 99.70% of the simulated scenarios, with no occurrence of infeasible cases, which demonstrates the high stability of the solution.

2 - A Multimodal Retrieval-Based Framework for Product Popularity Prediction in Fast Fashion

Sophie Liu, The University of British Columbia, Vancouver, BC, Canada, Xinhui Yu, Chunhua Wu

Accurate product popularity prediction is critical for reliable demand forecasting and inventory management, particularly in the fast fashion clothing sector. Existing approaches mainly employ computer vision techniques to extract high-dimensional visual features from clean clothing product images for predicting popularity, and often overlook other influential factors. As a result, they are prone to overfit and offer limited explainability. To address these challenges, we propose a multimodal retrieval-based framework for predicting product popularity that leverages design and pricing features. Specific fashion-related questions are used as prompts for ChatGPT to generate structured textual descriptions for each product. These descriptions, along with the corresponding product images, serve as inputs to a multimodal retrieval model. The retrieval module returns the top-k most similar popular and unpopular items for a given query, and we use similarity scores as features instead of raw image embedding to reduce input dimensionality. In addition to these similarity scores, we incorporate numerical features (e.g., discount level) and categorical features to build a multi-factor popularity prediction model. Through a case study on SHEIN clothes, our experimental results demonstrate the effectiveness of our proposed framework, highlighting its potential for supporting sustainable production strategies, and indicating the importance of multiple factors in shaping product popularity. Our findings support the employment of AI-driven decision-making to minimize overproduction and overstock in the fashion industry, with the potential to apply to broader fashion categories.

3 - A Robust Multi-Objective Model for Sustainable Closed-Loop Supply Chain of Home Appliances Under Demand and Return Uncertainty

Jorge Restrepo Diaz, Toronto Metropolitan University, Toronto, ON, Canada, Saman Amin

Corporate Social Responsibility (CSR) initiatives are increasingly influencing consumer behavior and shaping the management of Closed-Loop Supply Chains (CLSCs), the systems that integrate forward and reverse logistics in response to business, governmental, and societal pressures. As sustainability expectations rise, organizations are striving to incorporate environmental and social considerations into CLSC design. However, these efforts face challenges due to the often qualitative and uncertain nature of such metrics. This research addresses these challenges by proposing a comprehensive approach for designing a sustainable CLSC for home appliances, products essential for sustainable consumption that are impacted by rapid technological change and shortened product life cycles. The proposed model includes a Regime-Switching Lattice (RSL) framework to account for demand uncertainty and employs Material Flow Analysis (MFA) to assess return rates and the conditions of used products. Furthermore, a novel Multi-Objective Mixed-Integer Linear Programming (MOMILP) model is developed and integrated to simultaneously optimize economic performance, environmental impact, and social well-being. To solve the proposed model and generate Pareto-optimal solutions, this study utilizes an augmented ϵ -constraint method along with dynamic programming. The model is validated using real-world data from the three Canadian provinces of British Columbia, Ontario, and Quebec, and provides a robust decision-support framework for policymakers and supply chain managers aiming to design adaptive and sustainable CLSC for durable goods. The results show managerial insights into product allocation, facility location decisions, and reverse logistics strategies.

4 - Platform Competition and Incentives for Content Creators

Ruomeng Hu, Tianjin University, Tianjin, China, People's Republic of, Dan Ma, Nan Feng

Content platforms traditionally only offer monetary rewards to high-value creators who capture greater time engagement from content consumers. Recently, however, some platforms have begun extending their rewards to low-value creators. This study develops an analytical model to examine how such reward extensions affect creators' participation incentives, end-users' content consumption behavior, and platforms' profitability in a duopoly competition market. We consider two competing platforms that decide whether to extend rewards. Creators choose which platform(s) to join, while end-users choose a platform and allocate their time across creators. We find that reward extension might change creators' platform choices. Interestingly, the ultimate benefits may go to either the focal platform (due to competitive advantage) or/and the rival platform (due to the free-riding effect), depending on the degree of platform differentiation as well as the creators' costs of content production and multi-homing. In addition, we show that extending rewards to low-value creators can even benefit high-value creators when the platforms are highly differentiated, content is less substitutable, and the value gap between creators is small. When analyzing platforms' reward-extension decisions, we find that neither/one/both platforms extending rewards may all turn out to be possible equilibrium outcomes. For example, when low-value creators contribute reasonably significant revenue and when both content production costs and multi-homing costs are not high, only one platform extending rewards could be the equilibrium. Notably, platforms might face a prisoner's dilemma: under certain conditions, both will choose to reward low-value creators, even though both would be better off if neither does.

5 - Evaluation Methodology for Transfer Hub Capacity in Multi-Mode Rail Transit Systems Oriented to Coordinated Operation

Qinghui Xu, Tongji University, Shanghai, China, People's Republic of

As the core nodes connecting different types of rail transit systems, transfer hubs play a crucial role in determining the efficiency and service quality of multi-modal coordinated operation. However, current methods for evaluating the capacity of transfer hubs under multi-system conditions remain relatively coarse, lacking systematic, dynamic, and operation-oriented adaptability. This study, grounded in the concept of coordinated operation, develops a comprehensive capacity evaluation methodology tailored to transfer hubs within multi-mode rail transit systems. By integrating transfer behavior modeling, passenger flow-facility coupling analysis, and the correlation modeling of operational parameters, the proposed approach considers both static facility configuration and dynamic operational scheduling. Using empirical case studies from typical metropolitan transit hubs, the method is validated in terms of its effectiveness in improving capacity estimation accuracy, supporting facility optimization, and informing operational adjustments. The research provides theoretical support and technical tools for the coordinated optimization of regional rail transit networks and for investment decision-making regarding transfer hub infrastructure.

6 - Information Acquisition, Portfolio Choice, and Diversification

Jiming PAN, City University of Hong Kong (CityUHK), Shenzhen, China, People's Republic of, Xiao Qiao, Moris Strub

We study the joint decision of information acquisition and portfolio choice for a mean-variance investor. The investor is concerned with risk from both the information acquisition and investment periods. Optimal policies indicate that the investor should learn about assets with lower prior squared Sharpe ratios in order to improve the prospects of a diversified portfolio, because a concentrated portfolio is associated with an increased risk of extreme returns. Our results show that diversified portfolios can arise in a model without perfect information, suggesting that diversification has wider applicability than previously recognized.

7 - Can Algorithmic Opacity Tame the Generative AI Pricing and Leviathan? Endogenous Consumer Adaptation in AI-Driven Markets

li su, shanghai jiaotong university, shanghai, China, People's Republic of

Generative AI-driven dynamic pricing is transforming corporate pricing strategies, with algorithmic transparency critically shaping consumer adjustments in strategic waiting behavior under real-time AI-optimized pricing. This study develops a two-stage game-theoretic framework that integrates generative AI pricing algorithms with an endogenous time preference model to analyze strategic interactions between consumers and AI systems. We find that (i) While reinforcement learning-based pricing induces rational consumer expectations, algorithmic interpretability asymmetrically affects strategic behavior costs. Moderate opacity in pricing rules elevates prediction complexity, steering consumers toward myopic purchasing decisions and achieving mutual benefits across corporate profits, consumer surplus, and social welfare. (ii) Unlike static pricing models, AI-driven dynamic pricing mitigates price commitment inefficiencies through adaptive feedback mechanisms. However, excessive transparency reduces strategic deliberation costs, reinstating suboptimal "prisoner dilemma" equilibrium. (iii) Strategic costs can be endogenously amplified through complex pricing patterns (e.g. non-monotonic discounts), which systematically deter high-valuation consumers from strategic waiting. The results advance the design of AI-compatible pricing architectures by demonstrating how controlled information asymmetry optimizes market outcomes. Furthermore, the analysis reveals the dual role of generative AI as both an efficiency enhancer and a potential market destabilizer, contingent on algorithmic transparency levels. These insights inform regulatory frameworks for AI pricing systems, emphasizing context-dependent standards to balance innovation incentives with consumer protection imperatives.

8 - Robotic Slot-Shuffling Parking Reservation System: a Demonstration-Augmented Gflownet Approach for Revenue Optimization

hanyu qiu, chinese university of hong kong shenzhen, Shenzhen, China, People's Republic of, Pengyu Yan, Hongke Xie

Abstract: This study introduces a novel parking-reservation system supported by slot-shuffling robots. The system enables drivers to reserve parking slots in advance within a limited planning horizon, divided into multiple time periods. During each period, the system processes at most one reservation request with randomly parking duration (type) and decides whether to accept or reject it to maximize total revenue over the horizon. We model this problem as a Markov Decision Process incorporating a

robotic slot-shuffling mechanism to enhance resource utilization. To address demand uncertainty, we propose a model-free framework called Demonstration-Augmented Replay GFlowNet (DAR-GFN). This framework leverages offline first-come-first-served (FCFS) demonstrations to establish a robust navigation prior for the learning agent, while a prioritized replay buffer of top-revenue online trajectories is employed to update the joint backward policy, thereby improving sample efficiency and resilience to stochastic reservation arrivals. Numerical experiments using real-world parking demand data demonstrate that DAR-GFN significantly outperforms both the FCFS rule and deep reinforcement learning baselines from the literature.

9 - Topologically Enhanced Surrogate-Assisted Genetic Programming for Dynamic Flexible Flow Shop Scheduling with Parallel Machines

Yu Sun, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, Shenyang, China, People's Republic of, Ying Meng

Dynamic Flexible Flow Shop Scheduling with Parallel Machines (DFFSPM) is a challenging NP-hard combinatorial optimization problem critical for efficient resource utilization and productivity in modern manufacturing. Genetic Programming (GP) effectively evolves high-quality dispatching rules for such complex systems but suffers from computationally intensive fitness evaluations. Surrogate-Assisted Evolutionary Algorithms (SAEAs) mitigate this by approximating expensive fitness functions; however, their success largely depends on surrogate model accuracy, significantly influenced by the chosen feature representation. Traditional scheduling features, such as phenotypic characterization, often fail to sufficiently capture the complex characteristics of dispatching rules applied to DFFSPM problems. To overcome this limitation, this study introduces novel topological features derived through Topological Data Analysis (TDA) to enhance surrogate model accuracy. Specifically, during the GP process, candidate dispatching rules are evaluated using small-scale scheduling instances to efficiently generate representative resulting schedules. TDA techniques are then applied to extract robust topological features from these schedules, capturing deeper structural properties of the scheduling solutions. These extracted features form the basis for training more accurate surrogate models, significantly improving predictive capabilities. Numerical experiments on diverse DFFSPM problems with varying objective functions demonstrate that surrogate models trained with topological features achieve superior prediction accuracy. Furthermore, the enhanced surrogate-guided genetic programming framework consistently discovers higher-quality dispatching rules more efficiently, underscoring the substantial potential of integrating TDA within surrogate-assisted evolutionary algorithms.

10 - A Three-Phase Method for Systematically Computing Multiple Optimal Solutions of Nonlinear Constrained Optimization Problem

Cuiqing Zhang, Sun Yat-sen University, Guangzhou, China, People's Republic of, Yusi Zhang

In this article, a novel Three-phase method is proposed to systematically compute multiple local optimal solutions (LOSs) for constrained nonlinear optimization problems. It locates the feasible connected component (FCC) by reformulating the problem as the identification of the stable equilibrium manifold (SEM) of a Quotient Gradient System (QGS) and transforms the search for a LOS into the identification of stable equilibrium points (SEP) of a Projected Gradient System (PGS). In phase I, a FCC is identified via the QGS and a LOS is obtained on this component using the PGS. Phase II enables transition from the current FCC to another one. In Phase III, the PGS is again applied to find additional LOSs simultaneously on the new FCCs. This method offers systematic and deterministic exploration of multiple solutions, does not rely on initial values, and exhibits high computational efficiency. A theoretical foundation for both phase I and III is developed, and these theoretical results are quite general on their own. The proposed method is numerically evaluated to compute multiple LOSs, for instance, a step-by-step demonstration using a 2-D example. In addition, compared with interior point method, heuristic method, and other multiple-solution techniques, the proposed method can efficiently find the multiple or even global optimal solutions across various optimal power system problems with dimensions ranging from 10 to 1000.

11 - Dynamic Causal Modeling and Analysis of Risk Evolution in Vehicle-Nonmotorized Vehicle Interactions for Enhanced Driving Safety

zhangcun Yan, Tongji University, Shanghai, China, People's Republic of

In complex traffic scenarios characterized by high-density mixed flows of motorized and non-motorized vehicles, significant safety hazards exist that not only endanger vulnerable road users but also pose serious challenges for the practical implementation of autonomous driving technologies. To address this critical issue, this study innovatively develops a dynamic causal modeling and analysis framework designed to systematically investigate the generation mechanisms of risk sources and their causal pathways in the evolution of microscopic driving behavior risks during vehicle-non-motorized vehicle interactions. Specifically, this research makes three primary innovative contributions: First, we pioneer an eight-dimensional risk perception model for shared spaces that quantitatively characterizes the dynamic temporal features of vehicle-environment interactions through multidimensional feature parameters. Second, we introduce the advanced PCMC1 algorithm for dynamic causal inference, constructing both Anticipated Collision Time (ACT) and Conflict Risk Field (CRF) models based on interaction data from unprotected left-turn scenarios. Third, through time-lag effect analysis and causal pathway exploration, we reveal the intrinsic causal mechanisms between feature variables and conflict risks. Empirical results demonstrate that the dynamic CRF model exhibits superior risk evolution characterization capability, clearly identifying both positive reinforcement effects and negative attenuation effects in risk transmission. Notably, the dynamic causal CRF model achieves 1-2 second advanced risk prediction and precise risk source localization, providing reliable decision-making support for warning systems. These findings not only establish an innovative theoretical framework for driving safety warnings in complex mixed traffic environments, but also lay a crucial technical foundation for optimizing intelligent driver assistance systems.

12 - System Modeling of the U.S. Aluminum Supply Chain: Integrating Dynamic Material Flow Analysis and Life Cycle Assessment

Sidi Deng, University of Michigan, Ann Arbor, MI, United States, Daniel Cooper

The aluminum industry is a cornerstone of the global economy and contributes substantially to greenhouse gas (GHG) emissions. The ever-growing demand for aluminum underscores the need for a sustainable and low-carbon supply chain. Recognizing that regional contexts play a critical role in shaping supply chain dynamics, this study narrows its scope to U.S. aluminum production and consumption. An object-oriented model is established as a digital representation of the U.S. aluminum supply chain, which serves as a computational engine for simulating dynamic material flows and quantifying time-dependent carbon footprints associated with both domestic production and international trade. This presentation intends to showcase the emission performance outcomes from the model under various scenarios, featuring temporal emission breakdowns by supply chain stage, carbon source, and commodity, as well as the cradle-to-gate carbon footprint of each end-use product category. Three decarbonization pathways (e.g., electrification, hydrogen, and inert anodes) have been encoded into the model, with their performance evaluated from 2020 to 2050 under evolving energy profiles and climate-change initiatives. This study underscores the critical role of integrating material flow analysis and life cycle assessment in guiding sustainable supply chain planning and industrial decarbonization. It introduces a system-oriented analytical paradigm applicable to other material and energy intensive industries.

13 - A Two-Echelon Energy-Aware Routing Model for Truck–Drone Coordination in Mountainous Fresh Logistics

shunfeng zhang, Southeast University, China, Nanjing, China, People's Republic of, Xinlian Yu, xiaofeng li, haijun mao

The logistics of fresh agricultural products in mountainous regions are confronted with significant challenges, including complex terrain and weather conditions, limited cold chain and charging infrastructure, and low delivery efficiency. To address these challenges, we propose a two-echelon energy-aware truck-drone routing problem (TEDR). Specifically, trucks are responsible for direct deliveries to accessible demand points and serve as mobile bases for drone operations. Drones are dispatched from truck stops to reach multiple demand points that are inaccessible to trucks due to terrain or road constraints. A bi-level decision framework is developed to ensure effective coordination between trucks and drones, considering dynamic energy consumption. The upper level employs a CNN-Transformer hybrid model to predict drone energy consumption in real time, accounting for variations in terrain and weather conditions. The lower level constructs a bi-objective optimization model to minimize the total operational cost and the maximum delivery time, thereby enabling adaptive path planning for the truck-drone system.

To solve this complex problem, we design a Deep Reinforcement Learning-enhanced Multi-Objective Evolutionary Algorithm (DRL-MOEA). A case study using real-world data from the mountainous region of Kunming, China, demonstrates the effectiveness of the proposed approach. Our approach significantly reduces cost and time while improving solution quality and Pareto front coverage over conventional methods. System performance regarding key parameters such as energy consumption rate, delivery reliability, and operational robustness is also analyzed. These results confirm the effectiveness of the proposed framework and offer valuable insights into intelligent cold chain logistics in complex terrains.

14 - Trajectory Prediction and Risk Assessment in Car-Following Scenarios Using a Noise-Enhanced Generative Adversarial Network

Xinyi Li, The Hong Kong Polytechnic University, Hong Kong, China, People's Republic of, Ting Fu

Traditional conflict analysis methods, relying on the assumption of constant velocity, often fall short in capturing the dynamic nature of driver behavior randomness during the interaction process. Predicting all potential collision trajectories proves crucial for comprehensive safety analysis. To address the challenge of accounting for trajectory randomness in car-following scenarios, this study introduces a noise-enhanced generative adversarial network, named Car-Following GAN, designed for predicting collision trajectories based on data from the Shanghai Naturalistic Driving Study (SH-NDS). The model employs an encoder-decoder framework, integrating a noise enhancement module to capture the intrinsic randomness of driving patterns. Demonstrating notable robustness across varying environmental conditions, our model showcases adaptability for trajectory prediction in diverse driving scenarios. A conflict measure, termed the Rear-end Collision Risk Index based on Car-Following GAN (RCRIC), is proposed to quantify the risk of a rear-end collision. Our approach conducts a comprehensive case analysis to assess the impact of various traffic risk factors on RCRIC. The results underscore that our noise-enhanced approach significantly improves the trajectory prediction accuracy of the model when compared to other noise addition methods. This enhancement is observed across various prediction time windows and under different weather conditions. Moreover, RCRIC, derived from the model employing our noise-enhanced approach, effectively mirrors the dynamics of rear-end collision risk by explicitly incorporating trajectory randomness into its assessment. Furthermore, the findings underscore the significant influence of light conditions, traffic density, and weather conditions on driving risk.

15 - How Does China's Iron and Steel Industry Achieve Carbon Emission Reduction Goals? from the Perspective of Production Processes Optimization

Chen Wang, University of Science and Technology Beijing, Beijing, China, People's Republic of, Shufen Dai, Wei Gu

With the advancement of global carbon neutrality goals, the steel industry faces increasing pressure to reduce emissions. The limited scrap resources and high steel production demand necessitate the long-term coexistence and gradual substitution between the Blast Furnace-Basic Oxygen Furnace (BF-BOF) process and the Electric Arc Furnace (EAF) process in global steel industry. Therefore, a scientific evaluation of the emission reduction potential of BF-BOF and EAF process substitution and optimization, and the development of emission reduction pathways are of great significance for achieving the "dual carbon" goals.

Taking Chinese steel industry as an example, this paper explores the low-carbon technology pathway planning from 2023 to 2050 using a machine learning method and scenario analysis from the perspective of production processes optimization. We found that process optimization has played a role in reducing carbon emissions in the steel industry over the past decades. And by the low-carbon potential prediction of technologies, we found that the BF-BOF-based technologies have limited effectiveness, with carbon emissions decreasing from 2,199.95 MtCO₂ in 2023 to 1,025.27 MtCO₂ in 2050; while the EAF process scenario shows significant promise. The co-abatement scenario, supported by various technologies, represents a reasonable emission reduction pathway, projected to be more efficient and effective than that in the EAF process scenario. However, despite this, low-carbon technologies for process optimization are still unable to achieve the 2060 carbon neutrality target. Therefore, this paper also proposes the application strategies of mainstream emission reduction technologies for different processes at different stages while providing specific policy recommendations.

16 - Improving Front Distribution Center Fulfillment Rates: A Distributionally Robust Approach

Qingwei Jin, Zhejiang University, Hangzhou, China, People's Republic of, Haodong Feng, Man Feng, Qianqian Jin, Xinru Hao, Yidong Zhang, Lei Cao

In E-commerce distribution networks, front distribution centers (FDCs) are extensively employed to reduce delivery time, which has a significant impact on customers' purchase intentions and loyalty. Upon customer order placement, the corresponding FDC promptly fulfills the order, ensuring a short delivery time. If there is a shortage in the FDC, the order is then fulfilled by the regional distribution center (RDC) with a longer delivery time. Otherwise, a lost sale occurs. A key performance metric is the FDC fulfillment rate which reflects the proportion of orders successfully fulfilled by FDCs. In this paper, we design a distributionally robust allocation model that improves FDCs' fulfillment rates and, at the same time, maintains the region's overall fulfillment rate. We transform this model into an equivalent mixed integer second order conic programming (MISOCP) model, and an approximate mixed integer linear programming (MILP) model by partitioning the robust domain. Through numerical experiments, we investigate the impact of the balance coefficient on fulfillment rates and demonstrate the excellent performance of our model in a rolling horizon setting, particularly when faced with inaccurate demand forecasts. We implement our model within the distribution network of the home appliance industry of Tmall platform (the largest E-commerce retail platform in China), resulting in a notable improvement in the FDC fulfillment rate (exceeding 10%) and a substantial boost in gross merchandise volume (GMV).

17 - Research on Graph Convolutional Recommendation Algorithm Based on Hyperbolic Space and Contrastive Learning

Pengyu Lu, Harbin Institute of Technology, Harbin, China, People's Republic of, Zicheng Wang

To address the limitations of existing recommender systems in capturing hierarchical user preferences and handling long-tail item recommendations, we propose Hyperbolic Contrastive Graph Convolutional Networks (HC-GCNs). This architecture, built upon a 3-layer LightGCN and HyperGCN baseline, leverages hyperbolic space embeddings and contrastive learning to mitigate oversmoothing and data sparsity in graph-based recommendation models. We employ the Lorentz model to embed user representations in hyperbolic space, thereby capturing hierarchical relationships and enhancing long-tail item recommendation. Triplet contrastive learning is implemented to refine embeddings by minimizing the distance between user-target item embeddings and maximizing the distance between user-non-target item embeddings. We evaluate HC-GCNs using AUC, F1@K, Recall@K, and NDCG@K metrics on the MovieLens-10M and Amazon-Book datasets. Experimental results demonstrate that HC-GCNs outperform the baselines across all evaluation metrics. Specifically, on the Amazon-Book dataset, HC-HyperGCN exhibits a performance improvement exceeding 12.8% compared to HyperGCN.

18 - A Collaborative Production Planning Game in Steel Industry

Yuming Zhao, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Shengnan Zhao

In this work we introduce a collaborative production planning game inspired by real-world joint production processes in the steel industry, which requires complex coordination among companies of the same production stage but with varying capacities and demands, aiming to improve production efficiency and reduce costs. We introduce a column-generation-based algorithm specifically designed to identify a core allocation of among cooperating participants. A heuristic is proposed to solve the planning subproblem, which considers grouping, carryover, and backlogging in production processes. Numerical experiments are carried out and demonstrate the effectiveness of proposed models. The results indicate that the collaborative framework makes improvements in resource utilization and ensures fair and stable cost-sharing among participants.

19 - How Digital Transformation Shapes Firm Performance: a Meta-Analytic Integration of Resource-Based and Institutional Perspectives

Hongyu DUAN, Hong Kong Baptist University, Hong Kong, Hong Kong, Chenming Peng, Danny Wang, Yulin Fang

Digital transformation (DT) has become a critical driver of firm performance, enabling organizations to enhance operational efficiency, foster innovation, and strengthen customer engagement. However, despite its potential, the performance outcomes of DT vary significantly across contexts, highlighting the need to better understand the factors that shape this relationship. Drawing on the Resource-Based View (RBV) and institutional theory, this study examines how the configuration of DT strategies, defined by technology type (incremental vs. disruptive), scope (organization-wide vs. department-wide), and strategic orientation (impact-driven vs. effort-driven), moderates the DT-performance relationship. Additionally, we explore how institutional factors, including education level, internet penetration, power distance, rule of law, and economic growth, condition the effectiveness of DT. Using a meta-analytic approach, we synthesize 783 effect size estimates from 225 empirical studies conducted across 36 countries. This study contributes to the literature by integrating strategic and contextual perspectives to explain heterogeneity in DT outcomes. Practically, the findings offer evidence-based guidance on how firms can strategically configure digital initiatives and align them with institutional environments to enhance firm performance.

20 - Network-Based Pick-up and Drop-off Optimization for Shared Autonomous Vehicles

Sunyu Wang, Department of Urban Planning and Design, The University of Hong Kong, Hong Kong, Hong Kong, Fangyi Ding, Yineng Wang, Anthony Gar-On Yeh, Guan Huang

Shared autonomous vehicles (SAVs) are reshaping the mobility system, with ride-hailing services being regarded as a pioneering application market. Despite its benefits, SAVs inevitably exacerbate the competition for limited curb space, which is already a scarce resource. Designated pick-up and drop-off sites, if reasonably planned, present a promising solution to this challenge. In this paper, we propose a novel network-based data-driven approach to optimize PUDO locations for SAVs. Network kernel density estimation (NKDE) is used to measure the PUDO demand along the road network based on historical ride-hailing data. The results are fed into a maximal coverage location problem (MCLP) model to optimize the spatial distribution of PUDO sites by maximizing the demand they can cover. The spatial optimization model is used both prescriptively and descriptively, assessing transport policies and enhancing the operations of SAVs. Results show that our model outperforms the baseline models. We also reveal that a suitable PUDO site density is about 20/10 km², with denser sites in bustling urban centre and sparser sites in suburbs. The framework is highly generalizable and reproducible and can be extended to future studies.

21 - Asymptotic Optimality of Simple Policies for Serial Inventory Systems with Lost Sales: Beyond Echelon Base-Stock Policy

Huanyu Yin, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Xiting Gong

We consider a periodic-review serial inventory system, where demands are satisfied by the on-hand inventory of the lowest stage, and unsatisfied demand is fully lost. The objective is to minimize the long-run average holding and penalty costs. When unsatisfied demand is backlogged, [Clark and Scarf \(1960\)](#) prove that the Echelon Base-Stock (EBS) policy, maintaining a constant echelon inventory position in each period, is optimal. However, for the lost-sales setting, the optimal replenishment policy is notoriously complex and intractable due to the curse of dimensionality. Previous study focuses on the asymptotic analysis of the best EBS policy, which performs poorly when lead times are large or the unit penalty cost is relatively small. Hence, we propose two new classes of heuristic policies: Echelon Projected Non-stockout Probability (EPP)₃ and Echelon Project Inventory Level (EPIL) Policies. We prove that the best single-index EPP ₃ and EPIL policies are asymptotically optimal with large unit penalty costs under a broad class of demand distributions. Moreover, as external lead times increase, we establish a constant asymptotic bound on the relative optimality gap of the best dual-index EPIL policy, which admits a closed-form expression under exponential demand distributions. We also analyze how this gap behaves under strong demand pooling. To facilitate computation, we develop a sequential optimization method to obtain the sequentially optimized EPP ^{SO}₃ policy. Our numerical results show that all policies perform close to optimal and significantly better than the EBS policy.

22 - TCLMA: A Two-Dimension Contrastive Learning Based Multiagent Framework for Invention Novelty Evaluation

Lin ZHENG, City University of Hong Kong, Hong Kong, Hong Kong, Qingyu Xu, Jian MA

AI-supported methods are increasingly employed to measure human knowledge outputs, such as inventions. However, evaluating the creativity of inventions remains a persistent challenge. The notion of creativity, particularly invention novelty, is crucial for distinguishing significant scientific and technological advancements, spanning activities from basic research to groundbreaking innovations. Recently, the emergence of Large Language Models (LLMs) has been explored into their potential for assessing invention novelty. However, existing models depend heavily on implicit reasoning, which causes them to lean on the experiential knowledge encoded in LLMs. Meanwhile, time is a critical factor in determining whether an invention is truly new, a capability that current LLM-based methods inherently lack. This paper introduces TCL-MFSNE, an advanced multi-agent framework designed to address these challenges in invention novelty evaluation for patent assessments. TCL-MFSNE incorporates a two-dimensional contrastive learning module—comprising positive-negative contrastive learning for enhanced discrimination and temporal contrastive learning to account for the time-sensitive nature of invention novelty. By integrating these modules with explicit Chain of Thought (CoT) reasoning, TCL-MFSNE enables LLMs to systematically evaluate invention novelty while grounding their reasoning in both contemporary and historical contexts. Furthermore, the framework employs Byzantine Consensus theory, ensuring robust multi-agent collaboration for stable and accurate decision-making even in the presence of inconsistencies. Experimental results demonstrate that TCL-MFSNE achieves state-of-the-art performance, with an accuracy and F1-score of 85% on patent classification tasks. By addressing real-world challenges in invention novelty assessment, TCL-MFSNE advances the theoretical capabilities of LLMs and provides a practical tool for improving intellectual property evaluations.

23 - Operation Strategy for Styling Box Platform

Yuan Qu, University of Hong Kong, Hong Kong, Hong Kong, Max Z.J. Shen

Styling box selling has emerged as a novel online shopping format, shifting from traditional active browsing to a passive model where customers periodically receive curated selections of items. Customers can keep desired items and return the rest, often benefiting from a discount if they retain the entire box. This study investigates the platform's operational strategies—discount, recommendation, and pricing—critical to this unique business model. We develop a framework under the Stackelberg setting that captures the interplay between a profit-maximizing platform and strategic buyers with heterogeneous preferences. First, we analyze the buyer choice model and derive the corresponding platform profit model. Our analysis reveals some dominant item swap properties, which enable the discussion of the optimal recommendation strategy and characterize the properties of the optimal discount policy. Under this recommendation strategy, we further examine the optimal discount policy in a homogeneous pricing setting, providing a stylized model that offers a macro-level perspective and a simple estimation method for platform decision-making. Finally, numerical experiments validate our theoretical findings and explore the implications for optimal pricing strategies.

24 - Continuous and Monotone Bayesian Nash Equilibrium with Incomplete Information About Player's Risk Preferences

Ziheng Su, The Chinese University of Hong Kong (CUHK) - Department of Systems Engineering & Engineering Management, Hong Kong, Hong Kong, Huifu Xu

In this paper, we consider a non-collaborative game where each player faces two types of uncertainties: aleatoric uncertainty arising from inherent randomness of underlying data in its own decision-making problem and epistemic uncertainty arising from lack of knowledge and statistical information on the rivals' risk preferences. By assuming that players are risk-averse against aleatoric uncertainty and risk-neutral on the epistemic uncertainty, we propose a Bayesian risk minimization model to describe players' interactions. We investigate existence and uniqueness of a continuous monotone equilibrium arising from the game, termed CMBNRE, where "R" is used to emphasize the game is concerned with risk minimization as opposed to utility maximization in the existing BNE models. We derive sufficient and/or necessary conditions for ensuring existence of CMBNRE from two perspectives: monotonicity of a continuous BNRE and continuity of a monotone BNRE. Continuous BNE emphasizes continuity of each player's response function with respect to variation of the type parameter whereas monotone BNE focuses on monotonicity of the player's response function and/or rival's response functions. The former is derived by virtue of Schauder's fixed point theorem and the latter is established by other fixed point theorems based on single-crossing and quasi-supermodularity, the proposed CMBNRE model synthesizes the two modeling frameworks. We discuss numerical methods for computing an approximate CMBNRE from stochastic optimization perspective and apply the proposed model and computational schemes to a reinsurance competition problem. The test results provide some insights about how indemnity parameter may affect reinsurer's behaviour, market share and profitability.

25 - Condition Number Shrinkage by Joint Distributionally Robust Covariance-Precision Estimation

RENJIE CHEN, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Huifu Xu, Viet Anh Nguyen

We propose a distributionally robust formulation for the simultaneous estimation of the covariance and precision matrix of a random vector. The proposed model minimizes the worst-case weighted sum of Stein's loss of the precision matrix estimator and the Frobenius loss of the covariance estimator against all distributions from an ambiguity set centered at the empirical distribution. The radius of the ambiguity set is measured via convex spectral divergences. We show that the proposed distributionally robust estimation model reduces to convex optimization problems and thus gives rise to computationally tractable estimators. The estimators, as an outcome of distributional robustness, are shown to be nonlinear shrinkage estimators. The eigenvalues of the estimators are shrunk nonlinearly towards a scalar matrix, where the scalar is determined by the weight coefficient of the loss terms. We show that the shrinkage effect improves the condition number of the estimator. We provide the explicit expression of the shrinkage estimators induced by Kullback-Leibler divergence, Wasserstein divergence, Symmetrized Stein divergence, and Frobenius divergence. We also provide a parameter-tuning scheme that adjusts the shrinkage target and intensity that is asymptotically optimal. Numerical experiments on synthetic and real data show that our shrinkage estimators perform competitively against state-of-the-art estimators in practical applications.

26 - Navigating Endogenous Uncertainty in the New Energy Paradigm: Renewable Integration and Resilience Enhancement

Yunhe Hou, The University of Hong Kong, Hong Kong, Hong Kong

The accelerating integration of renewables and the rising frequency of extreme events have fundamentally shifted the uncertainty landscape in power systems. Classical reliability-oriented frameworks, designed for stable conditions, increasingly struggle as uncertainties from renewable variability and extreme events account for a dominant share of system risks. We will introduce resilience-oriented scheduling and planning approaches that break traditional reliability constraints by embracing and proactively managing these high-impact uncertainties. A central focus is on identifying and modelling Decision-Dependent Uncertainty (DDU), where strategic decisions—such as renewable siting, grid reinforcement, or maintenance scheduling—directly shape future uncertainties by altering congestion patterns or failure probabilities. To address the dimensionality and non-convexity challenges inherent in DDU, we present new computational methods based on scenario-based reformulations and tractable approximations. Case studies demonstrate how these approaches enable power system planners to anticipate, influence, and mitigate extreme-event-driven uncertainties, offering a transformative path toward resilient, renewable-rich grids.

27 - Price Competition in a Duopoly with Three Vertically Differentiated Products

Masashi Umezawa, Tokyo University of Science, Chiyoda-ku, Tokyo, Japan, Ryoga Ishihara

This study investigates price competition in a duopoly market where each firm offers three vertically differentiated products—low, medium, and high quality. While existing research has primarily focused on product lines with only two types, considering three quality levels is more realistic, given the presence of a middle segment of consumers. The paper addresses several key questions: How do firms set prices for three products while mitigating cannibalization? How do consumer preferences and production costs affect equilibrium prices and profits? Do equilibrium profits rise when firms offer three products instead of two? If so, under what conditions?

The paper develops a model of horizontal and vertical differentiation in a duopoly and yields two primary findings. First, regarding comparative statics, while higher marginal costs typically reduce profits, the analysis shows that, under certain conditions, increasing the marginal cost of one product can increase profits due to strategic interdependence and demand substitution across products. Specifically, when the marginal cost of the medium-quality product (M) is low, profits can rise with increases in the marginal cost of either low (L) or high (H) quality goods. When M's cost is high, increasing M's cost can also raise profits.

Second, comparing two-product and three-product strategies, the study identifies conditions under which firms earn higher profits with three products. These depend on the relative differences in marginal costs across goods and on which product becomes more cost-effective to sell. The analysis provides clear thresholds for these outcomes.

28 - Structured I/O Design for Modular Scheduling Experiments

Juntaek Hong, Pohang University of Science and Technology, Pohang, Korea, Republic of, Kangbok Lee

This study proposes a structured I/O approach for scheduling experiments, aiming for rapid development and traceability. The modular use of multiple DataFrames reflects the inherently tabular structure of widely-used benchmark datasets, reducing the overhead of reading and transforming raw text into model-ready formats. Traceability is enhanced through a solver logger that captures parameter settings and performance metrics over time. This also approach supports modular experimentation and transparent reporting. Future work includes open-sourcing tools and broader validation across commercial solvers.

29 - Developing a Screening Methodology for Dedicated Freight Truck Lanes Using Transportation Big Data and Traffic Simulation

GwanYong OH, Inha University, Incheon, Korea, Republic of, Sungmin Kim, Daejin Kim

This study proposes a methodology for identifying candidate sections for dedicated freight truck lanes by integrating big transportation data with traffic simulation techniques. Utilizing real-world traffic volume data from the Korea Transport Institute's View-T system, the analysis evaluates traffic and environmental factors across the national road network. Thirteen key indicators—including freight vehicle ratio, average speed, congestion intensity, and pollutant emissions—were selected, normalized using Min-Max scaling, and aggregated into a composite Screening Score. Based on this score, high-priority road segments were systematically identified. The prioritization process was further refined by incorporating road attributes such as road classification, with weighted adjustments reflecting freight traffic volume to better capture freight-dense corridors. To assess the potential impacts of implementing dedicated freight lanes, top-ranked sections underwent microscopic traffic simulation analysis using VISSIM, evaluating metrics such as changes in average speed, congestion relief, emissions reduction, and traffic safety improvements. This study presents a practical and data-driven analytical framework that supports both strategic screening and simulation-based policy assessment for freight infrastructure planning.

30 - Deep Learning-Based Staging and Grading of Periodontitis Using Geometric Features from Panoramic Radiographs

Jae Jun Lee, Department of Industrial and data engineering, Hongik University, Seoul, Korea, Republic of, Yong Oh Lee, Kyeong Won Paeng, Jae Kook Cha

Periodontitis is a chronic condition that causes tooth and alveolar bone loss and affects a large portion of the global population. Traditional diagnosis depends on visual assessments by clinicians, resulting in high variability and limited consistency. While deep learning-based approaches have been explored, their diagnostic performance often falls short for clinical use.

We present a deep learning system for automated staging and grading of periodontitis using panoramic dental radiographs. Unlike prior methods that measure periodontal bone loss (PBL) at a single mesial site, our approach computes the PBL-to-CEJ (Cemento-Enamel Junction) ratio at two parallel-offset endpoints of each tooth, improving anatomical accuracy and staging reliability.

Multiple U-Net-based segmentation models were evaluated to extract tooth and PBL/CEJ boundaries, and the best-performing model was used to compute staging scores. The maximum per-patient score determined disease stage, while length-based features enabled longitudinal comparison of follow-up images for clinical grade assignment.

Experimental results demonstrated improved staging accuracy over previous methods and reliable discrimination of severe cases, supporting the system's potential as a clinical decision aid in dental diagnostics and treatment planning.

31 - Optimal Behavior-Based Load Balancing Under Re-Tou Pricing: Understanding Latent Classes’ Temporal EV Charging Preferences

Bo-Eun Choi, Korea university, Seoul, Korea, Republic of

Although renewable energy production as an alternative to fossil fuels is increasing globally, electricity generated from renewable sources is often curtailed because of temporal imbalances between supply and demand in energy systems. In response, demand-side strategies that shift electricity consumption across temporal periods enhance the system efficiency without major supply side alterations or investments. Consequently, strategies focusing on shifting consumer EV charging patterns—transferring demand from nighttime to periods of high renewable energy availability, mainly daytime—are gaining attention. In this context, the heterogeneity of user behavior is considered to identify group characteristics by segmenting consumers. This study employs a discrete choice experiment (DCE) to analyze consumer preferences regarding EV charging behavior, utilizing survey data from approximately 1,033 participants. Subsequently, latent class analysis (LCA) was conducted to identify distinct user segments and their temporal charging preferences.

Specifically, this study proposes Renewable Energy Time-of-Use (RE-ToU) pricing that incorporates real-time renewable energy share information with pricing signals, thereby delivering both economic and environmental signals to consumers. Through temporal charging probabilities according to these signals, we identified group-specific contributions, namely the amount of behavioral shift toward daytime charging periods. Subsequently, an empirical analysis of temporal grid stability is conducted based on the charging demand affected by consumer preferences, enabling the identification of time-varying demand-supply patterns according to demand fluctuations. The findings provide policy implications for designing demand-side management strategies that promote behavioral transitions in renewable energy systems.

32 - The Approximation Ratio of The Multifit Algorithm: a Computer-Assisted Proof

Insoo Park, POSTECH, Pohang, Korea, Republic of, Kyungduk Moon, Kangbok Lee

The identical parallel machine scheduling problem to minimize the makespan is a classic NP-hard problem in scheduling theory. Among its approximation algorithms, the MULTIFIT algorithm, proposed over four decades ago, remains particularly notable. However, its exact approximation ratio remains unresolved for certain numbers of machines, leaving long-standing open questions. In this work, we present a computer-assisted proof framework based on mathematical programming to verify the approximation ratio of MULTIFIT for all previously open cases.

33 - Cost-Effective Planning of Accelerated Degradation Reliability Demonstration Tests Based on Degradation Model Selection

Hyojung Kim, Chosun university, Gwangju, Korea, Republic of, Seong-joon Kim

Reliability Demonstration Tests (RDTs) are widely used during the product development stage to verify whether a product meets its required reliability level. However, for highly reliable products, traditional lifetime-based RDTs often require excessive time and cost, making them impractical for real-world implementation. To address this challenge, Accelerated Degradation Tests (ADTs) have been increasingly adopted, leading to the design of Accelerated Degradation Reliability Demonstration Tests (ADRDTs) that shorten test durations by accelerating the degradation process.

A key element in ADRDT planning is the selection of an appropriate degradation model. This study presents a practical guideline for selecting between two major degradation modeling approaches: the General Path Model (GPM) and the Stochastic Process Model (SPM). Based on the selected model, a cost-effective ADRDT plan is proposed, which explicitly considers both producer's and consumer's risks.

To evaluate the proposed method, sensitivity analyses and operating characteristic (OC) curves are provided using various numerical examples. Additionally, the practical applicability of the approach is demonstrated through a real-world case study using degradation data from an automotive Electronic Control Unit (ECU). The proposed methodology helps reduce testing burden while ensuring statistical confidence in reliability demonstration.

34 - Adaptation of A Multi-Task Learning Strategy for Tool Wear Estimation Paired with Cutting Force

hyein kim, Korea Institute of Industrial Technology, Ansan-si, Korea, Republic of, Soohyun Nam, Jeongin Koo

The deployment of online tool condition monitoring and machine diagnostics is critical to achieving sustainable manufacturing. Accurate tool wear prediction enables automated tool replacement by comparing real-time wear against predefined tool life limits, thus enhancing productivity and reducing costs. This study proposes a multi-task learning (MTL) framework that simultaneously estimates tool wear and cutting force, improving both monitoring accuracy and efficiency. Cutting force, a key indicator of tool condition, machining stability, and surface quality, is monitored in real time. Its mean and variance are used as target variables alongside tool wear, forming a joint prediction objective. Data are collected from multiple sensors and the CNC system, with meaningful features extracted through signal processing techniques. To validate the proposed MTL approach, we develop models based on Long Short-Term Memory (LSTM), Gated Recurrent Unit (GRU), and Temporal Convolutional Networks (TCNs). Model performance is evaluated in terms of accuracy, parameter size, and computational cost (FLOPs), and is compared against single-task learning (STL) models. Our results highlight the importance of inter-task correlation, demonstrating significant accuracy gains in the MTL models across architectures. This work provides an effective strategy for applying MTL to machining processes, contributing to intelligent and efficient manufacturing.

35 - Covariance Aligned Gaussian Process

Juhuhn Kim, KAIST, Daejeon, Korea, Republic of, Jong-Seok Lee

Gaussian process (GP) is a widely used statistical modeling technique for its nonparametric flexibility and ability to quantify uncertainty. However, standard GP typically assumes identical training and test distributions, making transfer from abundant source domain to scarce target domain challenging. To address this, we introduce Covariance Aligned GP (CAGP) framework that (1) induces functional priors from source domain, (2) aligns source and target second-order statistics via joint covariance alignment, and (3) performs a Bayesian update on the scarce target observations. By explicitly matching covariance structures, CAGP preserves rich source-domain structure while robustly adapting to the target domain under concept shift. Across multiple benchmarks, CAGP shows competitive predictive performance on scarce target data. This framework can be applied to a wide range of regression problems under concept shift or domain adaptation in simulation and real-world settings.

36 - Research on Optimal Technology Selection Paths for the Global Steel Industry to Reduce Greenhouse Gas Emissions

Yoonmo Koo, Seoul National University, Seoul, Korea, Republic of, Hyunkyung Joo

The global steel industry, responsible for approximately 7% of total greenhouse gas emissions and nearly 30% of industrial sector emissions, is under increasing pressure to decarbonize in alignment with global net-zero targets. With steel demand projected to grow by about 30% by 2050, reducing production is not a feasible mitigation pathway. Instead, the industry must pursue technological shifts such as hydrogen-based direct reduced iron (DRI), electrification, carbon capture, utilization and storage (CCUS), and bioenergy solutions.

This study develops an optimization model using Positive Mathematical Programming (PMP) to quantitatively evaluate the evolution of technology choices in the steel sector across six major producing regions: South Korea, China, Japan, the United States, the EU15, and India. The model incorporates dynamic learning-by-doing effects, allowing technology costs to decline as cumulative deployment increases, thereby capturing the cost competitiveness transition over time. PMP overcomes the corner solution limitations of linear programming by reflecting realistic, multi-technology adoption behaviors in industrial decision-making.

The analysis examines two learning scenarios—presence or absence of learning-by-doing, and differing learning rates based on conservative and progressive assumptions—to assess their impact on low-carbon technology adoption. Learning effects notably enhance the competitiveness of high-cost options like hydrogen and electrification, with adoption timing varying by country due to differences in resources and infrastructure. This research contributes to policy and investment decision-making by offering a dynamic and regionally differentiated perspective on future steel decarbonization strategies. It provides a robust analytical foundation for designing flexible, long-term pathways aligned with carbon neutrality goals.

37 - VPP Bidding and Operation in Electricity Markets Based on Stochastic Dual Dynamic Integer Programming

YoungDoo Choi, Pohang University of Science and Technology, Pohang-si, GYEONGSANGBUK-DO, Korea, Republic of, Sanghyeon Bae, Seokwoo Kim, Dong Gu Choi

The growing penetration of renewable energy in electricity markets has necessitated the introduction of a real-time market between the day-ahead market and actual electricity dispatch. Optimal decision-making for day-ahead and real-time bidding, as well as realtime operations, can be formulated as a scenario-based multi-stage stochastic programming problem. This problem is complicated by the possibility of negative prices due to excessive renewable generation, the non-convex nature of payment functions, and the temporal mismatch between real-time bidding and operations. Given the problem's 25-stage structure and inherent non-convexities, we adopt a formulation amenable to Stochastic Dual Dynamic Integer Programming (SDDiP).

To address the dependency of real-time prices on corresponding day-ahead prices, and to mitigate the high dimensionality of state variables induced by multi-dimensional dayahead prices, we propose a hybrid framework that integrates two-stage stochastic programming with SDDiP. We expect this approach to more effectively capture the coupled structure of day-ahead and real-time markets, and to outperform conventional SDDiP in such integrated market environments.

38 - Assessing Decarbonization Strategies in the Global Cement Industry: A Multi-Regional Optimization Approach

Byoungchan Chun, Seoul National University, Seoul, Korea, Republic of, Jonghyeok Han, Yoonmo Koo

The cement industry accounts for approximately 7% of global industrial greenhouse gas emissions and is considered one of the three major high-emission sectors along with steel and petrochemicals. As such, it is facing increasing pressure to reduce emissions in line with Nationally Determined Contribution (NDC) of each country. This study evaluates the feasibility of emission reduction targets in the cement industries of six major regions: South Korea, China, Japan, the United States, India, and the European Union. Key reduction technologies which are applicable to the cement sector—such as Energy efficiency improvements, Eco-friendly fuels, Decarbonated raw materials, and Carbon Capture, Utilization, and Storage (CCUS)—were identified and analyzed. The assessment was conducted using a process-based optimization model developed in GAMS, considering prediction for each country's demand for cement and emission reduction goals. Based on this framework, the study investigates the emission reduction pathways due to the technology selection and the feasibility of achieving NDC targets. In addition, scenario analyses were performed to assess the impact of policy changes, such as adjustments to emission goals and the introduction of carbon pricing, in order to test the impact of such changes on the emission goals

and pathways. The findings of the study provide a quantitative basis for the insights into the effectiveness of policy instruments such as incentive for some key technologies and introducing carbon taxes.

39 - Structuring AI Service Context: A Framework for Systematic Idea Generation

Geun hyeon Han, Incheon national university, Incheon, Korea, Republic of, Do-Hyeon Ryu

Artificial intelligence-based services (AIS) use autonomous learning and adaptive capabilities to predict user behavior and deliver personalized experiences. However, this innovation complicates the service context, which refers to the circumstances surrounding user-service interactions. As AIS processes various information, including environmental factors and interaction modalities, the number of contextual elements increases dramatically, and their combinations vary across services. Consequently, inadequate consideration of this context during the design phase leads to poor user experience and increases the risk of AIS design failure. To address this challenge, this study proposes a two-step framework for structuring the AIS context and applying it to design. First, GPT-4o-based few-shot information extraction analyzes literature to derive the relevant contextual dimensions and parameters. The extracted information forms a morphological matrix serving as the theoretical foundation. Second, real company cases and news data are mapped to this matrix to construct networks. Network analysis identifies dense connections as established service patterns with potential feasibility, while link prediction algorithms identify potentially viable, unexplored connections as candidate AIS opportunities. This study proposes a framework for structuring AIS context and a data-driven methodology for identifying novel service opportunities to support early-stage design decisions.

40 - A Pod Transfer, Repositioning, and Robot Scheduling Problem in the Robotic Mobile Fulfillment System by Deep Reinforcement Learning

Byung Soo Kim, Incheon National University, Incheon, Korea, Republic of, Yong Jae Kim

A robotic mobile fulfillment system (RMFS) is one of the parts-to-picker systems adopted by many e-commerce companies due to its efficient order processing and flexibility in response to changes in demand. We address a pod transfer, repositioning, and robot scheduling problem in the robotic mobile fulfillment system. The objective is to minimize the makespan, the time the last pod returns to the storage location. To solve the problem, we propose a rule-based deep reinforcement learning algorithm for a dynamic RMFS environment. The reinforcement learning network dynamically selects the decision rules to apply when choosing a storage location for the pod to return to after completing its picking operation. Compared to other rule-based heuristic algorithms and meta-heuristics, the deep reinforcement learning algorithm with several decision rules obtains comparative results in large-sized problems. We analyze the proportion of rules selected in the deep reinforcement learning algorithm and the impact of the pod storage and transfer policies on the productivity of RMFS.

41 - A Bi-Level Service Capacity Planning Model with Interdependent Mdp Followers

Seokwoo Kim, Pohang University of Science and Technology, Pohang-si, Korea, Republic of, Dong Gu Choi, Yuin Moon

This talk presents a bi-level service capacity planning model with sequential-decision-making followers. This model has an important application to on-demand platform's planning problem on a service network. In the model, followers (servers) are homogeneous and their problem is formulated as constrained semi-markov decision process (SMDP) model, where reward and resource constraint budget are determined by a leader's integrated compensation and staffing problem. Further, we consider dependent followers whose interactions are reflected on sojourn time, which becomes another decision variable. Extending on a fluid-based stylized equilibrium model developed in the literature, we propose a structured bi-level program model which admits a mixed-integer bi-linear single-level reformulation. Then we derive a novel mixed-integer linear reformulation exploiting problem specific insight, along with useful valid inequalities. Further, we identify an interesting relationship between our model and network-design models. Based on this observation, a dantzig-wolfe decomposition-based solution method is developed.

42 - The Effect of Interaction Quality on Customer Satisfaction Across Response Methods: The Mediating Role of Experience Quality (EXQ)

Seonghyeon Han, Korea University, Sejong, Korea, Republic of, JAESEOK YUN, Sung Yeon Kim, Jinmin Kim

With the advancement of digital technologies and the proliferation of contactless services, organizations are increasingly adopting diverse customer interaction modes. As a result, the way customers experience and evaluate services is also evolving. This study aims to compare how different customer interaction modes—human agents, generative AI-based chatbots, and automated response systems (ARS)—affect customer satisfaction. In particular, it examines whether experience quality (EXQ), defined as the customer's emotional and holistic perception of service experience, mediates the relationship between interaction quality and satisfaction.

Interaction quality is measured through responsiveness, reliability, and communication quality, while EXQ consists of product experience, outcome focus, moments of truth, and peace of mind. A survey was conducted for each interaction type, and structural equation modeling was employed to analyze how each mode influences perceived service quality and behavioral intention. The mediating role of EXQ was also statistically tested.

This study contributes to the theoretical understanding of how technology-driven service interactions shape customer experience mechanisms. Additionally, it provides practical implications for designing interaction strategies in service environments where accuracy, consistency, and adherence to standardized procedures are critical.

43 - Constructing Profitable Master Surgery Schedules Using Column Generation-Based Primal Heuristics

Samuel Bakker, Ghent University, Ghent, Belgium, Broos Maenhout, Babak Akbarzadeh

In this research, a column generation-based math heuristic is developed that is used to solve the case mix planning problem (CMPP) whilst creating a master surgery schedule (MSS) in an integrated manner. Current literature often still treats these two as separate problems, that are solved in a sequential manner. In our study, we solve these problems in an integrated fashion. The proposed math heuristic is used to solve this problem by considering the most relevant resources in a hospital such as wards and medical staff. The CMPP focuses on finding a mix of DRGs to target that maximizes a hospital's profits, whereas the MSS allocates operating room time among surgical disciplines. The constructed MSS accounts for the amount of required operating room time for each discipline, surgical discipline preferences, and potential setup-times when two different kinds of procedures are conducted after each other in the same operating room. The developed math heuristic iteratively generates new columns, improving the incumbent. Computational experiments showcase the performance of the math heuristic against diving heuristics, the restricted master heuristic, and an MIP.

44 - Examining Opinion Dynamics on Social Media: An Agentic Simulation

Atreyi Kankanhalli, National University of Singapore, Singapore, Singapore, Prakash Sukhwal, Pratyush Yadav

The rise of social media platforms has profoundly altered public discourse and opinion formation, offering new avenues to understand social dynamics and collective behaviors. Online platforms such as X serve as forums where diverse viewpoints collide, leading to potential risks such as polarization, misinformation spread, and fragmentation. Understanding the nature of opinion evolution on such platforms is crucial for mitigating the negative consequences.

Traditional opinion dynamics models in the literature struggle to capture the complexity of real-world conversations. These models are often limited by simplifying assumptions, failing to represent the nuances of realistic conversations. Furthermore, earlier agent-based models are typically unable to account for conversational contexts.

We address these limitations by employing large language models (LLMs) as agents in synthetic social media discussion simulations, enabling more naturalistic conversations and opinion exchanges. Particularly, we investigate the critical role of moderators—individuals who guide discussions and manage information flow. Additionally, network structure properties govern information dissemination patterns across different topologies. Another salient determinant of the discourse is the nature of the discussion topic.

Our methodology manipulates these three key factors: (1) moderator presence, (2) underlying network structure (scale-free versus small-world), and (3) discussion topic nature. Through this approach, we address questions of : How does the presence of moderators influence opinion change? How does network structure affect opinion dynamics? How do different topics impact opinion change?

This study offers research contributions and insights into fostering healthier social media environments by uncovering the interplay between moderation, network structure, and topic characteristics in shaping opinion change.

45 - Recurring Recalls and the Decision to Reshore: A Behavioral Theory of the Firm Perspective

Di Liu, University of Bristol, Bristol, United Kingdom, Minhao Zhang, Di Fan, Bangdong Zhi

Reshoring antecedents' literature recognized the essential role of quality issues in driving firms' reshoring behaviors; yet, it largely failed to consider the temporal conditions and persistence of quality underperformance. Through the lens of the behavioral theory of the firm (BTOF), we argue that the persistence of quality underperformance contributes to shaping firms' reshoring decisions. We test our theory by empirically examining the relationship between the persistence of product recall events and firms' reshoring behaviors based on the panel data of 479 publicly traded U.S. firms from 2004 to 2021. We find that the probability of firms engaging in reshoring initially decreases over a period of 3.997 years and then increases as the persistence of product recall crisis persists beyond this threshold. We further find that the U-shaped relationship becomes flatter when firms perform strongly financially but steeper when they experience financial struggles. Our study contributes to reshoring and BTOF literature by exploring the role of quality underperformance persistence in inducing firms' reshoring behaviors. Our study also adds to BTOF studies by examining the interaction between financial attainment discrepancy and the persistence of quality underperformance in affecting firms' problemistic searches. Our findings indicate that managers should shed light on how the length of quality issues conditions firms' responses and their possible nonlinear relationship underlined in decision-making.

46 - Operations Research as the Backbone of Intelligent Disaster Management

Nasrin Asgari, Anglia Ruskin University, Cambridge, United Kingdom, Jihee Kim, MD Shah Newaz, Reza Zanjirani Farahani

The increasing complexity and frequency of disasters have driven the evolution of disaster management into an interdisciplinary domain, integrating OR with emerging intelligent technologies. This study builds upon a comprehensive review by Gupta et al. (2016)*, which mapped disaster management research through OR methods such as mathematical programming, simulation, and network optimization. Recent advances have seen OR frameworks synergize with Artificial Intelligence (AI), big data analytics, Geographic Information Systems (GIS), Unmanned Aerial Vehicles (UAVs), social media, augmented/virtual reality (AR/VR), deep learning, cloud computing, robotics, and digital strategies. This integration enhances decision support across all disaster phases—prevention, preparedness, response, and recovery.

In prevention and mitigation, AI-driven forecasting and GIS-based spatial analytics inform OR-based risk models and infrastructure planning. Preparedness benefits from simulation and optimization, enriched by AR/VR for immersive training. During response, real-time data from drones, sensors, and social media are incorporated into OR-driven dynamic routing, resource allocation, and decision-support systems. Recovery phases apply OR models to optimize logistics, infrastructure restoration, and resource distribution, supported by big data and cloud computing.

This synthesis positions OR not only as a set of analytical tools but as the core integrative framework that structures, optimizes, and enhances intelligent decision-making in disaster environments. By integrating both data-driven AI insights and optimization-based decision models, OR ensures that disaster management systems are adaptive, efficient, and effective in real-time, complex scenarios. The study demonstrates the importance of continuous collaboration between OR researchers, technology developers, and disaster response practitioners.

47 - Data-Driven Chance-Constrained Mixed Integer Nonlinear Bilevel Optimisation via Copulas

Syu-Ning Johnn, University College London, London, United Kingdom, Hasan Nikkhah, Meng-Lin Tsai, Styliani Avraamidou, Burcu Beykal, Vassilis Charitopoulos

Process supply chains consist of planning and scheduling as two integral components. The presence of challenges in real-world demand data, such as multivariate data dependency and correlations, noisy data distributions, and parameter uncertainties can significantly complicate the decision-making process, making it difficult to identify feasible solutions. This necessitates the adoption of data-driven optimisation approaches to effectively account for the dependency structures inherent in the observed data to efficiently explore solution spaces and identify high-quality outcomes.

This work proposes a data-driven chance-constrained data estimation framework that integrates chance-constrained programming (CCP) with copulas. CCP is an optimisation-based method enforcing stochastic constraints under specified risk thresholds. Copulas is a non-parametric technique designed to estimate data while capturing the dependence structure among multiple uncertain parameters with inherent correlations. The proposed framework leverages the strengths of both methods to achieve high accuracy in modelling variable dependencies across different scenarios, especially when data exhibit complex distributions or non-trivial dependencies.

In this work, we focus on three integrated case studies originated from the planning and scheduling of process supply chains and crude oil scheduling. We integrate our proposed estimation framework with the Data-driven Optimisation of bi-level Mixed-Integer NONlinear problems (DOMINO) framework, which is a data-driven grey-box algorithm for addressing bilevel optimisation problems, to derive decisions with guaranteed demand satisfaction rates. Computational experiments demonstrate that our proposed copula-based chance-constrained optimisation framework can incorporate demand correlation and achieve higher joint demand satisfaction rate, lower total costs with higher efficiency.

48 - Counterfactual Recourse Fairness and Feasible Actions with Causality

Shiqi Fang, University of Edinburgh, Edinburgh, United Kingdom, Zexun Chen, Jake Ansell

Machine learning is widely used in credit risk assessment for its efficiency, accuracy and generalizability, but interpretability and fairness concerns have become critical. Most counterfactual-fairness methods focus on prediction and ignore applicants denied credit—those who most need actionable recourse—while Operational Research approaches rely on purely statistical classifiers that lack causal structure. Consequently, their counterfactual explanations neither respect feature causality nor translate into real-world decision processes. We introduce a novel causal framework that unifies counterfactual fairness with interpretable recourse, asking: if a rejected female were counterfactually male, would she need less effort to gain approval, and can we offer a more diverse, feasible and equitable set of actions? Our model embeds a structural causal model, beyond minimizing recourse cost, and optimizes the number and diversity of actionable changes. To guard against biases from measurement error and model misspecification, we employ multiple generation techniques—Gaussian methods, conditional variational autoencoders and other state-of-the-art approaches—enabling robust performance in deterministic or uncertain causal settings. Supporting both distribution- and point-based counterfactuals for discrete and continuous data, our framework is especially suited to credit applications. Experiments on multiple credit scoring and synthetic datasets demonstrate consistent gains in fairness, interpretability and robustness, empowering rejected applicants with transparent, equitable pathways to approval.

49 - Learning to Trust OR Trusting to Learn? Transparency and Mutual Adaptation in Human-AI Diagnostic Collaboration

Xinyu Li, Durham Business School, Edinburgh, United Kingdom, Li Ding, Yanlu Zhao, Shuyang Wu, Timothy Kendall

This study investigates how clinicians interact with AI explanations in real time, and whether mutual learning—adaptation by both humans and AI—can emerge through repeated collaboration. Specifically, we examine how different formats of AI transparency influence diagnostic decisions, trust, and cognitive engagement in a high-stakes medical context. While many clinical AI tools prioritize accuracy, few studies explore how clinicians interpret and use AI outputs, particularly when explanations vary in complexity. We conduct a within-subject, multi-phase experiment with practicing pathologists. The study compares behavior across three transparency conditions: (1) AI prediction only, (2) prediction with key diagnostic markings, and (3) prediction with chain-of-thought reasoning. We track decision changes, interaction timing, and reasoning engagement to examine whether more explanation leads to better adoption—or cognitive overload. In a follow-up phase, clinicians evaluate the same cases without AI to assess whether earlier exposure to AI reasoning influences their independent diagnostic behavior. Findings from this study will provide empirical evidence on how to balance transparency with usability, and whether mutual learning occurs between humans and AI. The results aim to inform the design of explainable AI systems that support clinical adoption, improve human-AI collaboration, and bridge the gap between technical interpretability and real-world effectiveness.

50 - Pricing in Live Streaming E-Commerce: Integrating Customer Type Analysis

Yuan Dong, Temple University, Philadelphia, PA, United States, Guohou Shan, Subodha Kumar

Live streaming e-commerce (LSE) gradually becomes the future of shopping and creates hundreds of billions of markets. Influencers can demonstrate the product and interact with potential consumers in real-time on LSE platforms, reducing product uncertainty and raising the consumers' purchasing intention. In this research, we focus on understanding how online stores alter LSE frequency and pricing decisions to boost their revenue better. To better understand consumers' decisions, we also categorize consumers into product-oriented and influencer-oriented, aiming to understand the impact of consumer heterogeneity on store decisions. Our research makes both theoretical and practical contributions. On the one hand, we enrich the prior literature by focusing on exploring more nuanced decisions that a store can make regarding the LSE setting and adoption while considering customers' heterogeneity. On the other hand, our research findings can help online stores make better decisions and strategies as for leveraging LSE to boost their product sales and revenue.

51 - Surviving and Thriving: Firm Resilience in Competitive and Uncertain Markets

Zhide Wang, Southern Methodist University, Irving, TX, United States, Yanling Chang, Nathan Yang, Alfredo Garcia

This paper develops a dynamic equilibrium model to evaluate growth resilience—the ability of a firm to consistently expand operational capacity across both favorable and unfavorable economic environments. Recognizing that macroeconomic conditions cannot be exactly observed and must be inferred through noisy economic indicators, we formulate the problem as a partially observable stochastic game (POSG), allowing firms to update beliefs about the underlying economic states and make capacity expansion decisions accordingly. We provide theoretical identification results and develop a likelihood-based estimation method to recover the model's structural parameters. Applying this framework to study the influence of partially observable macroeconomic states on the Canadian fast-food industry from 1970 to 2004, we quantify firm-level growth resilience and find that while many firms demonstrate positive profitability across macroeconomic states, the dominant firm (McDonald's) exhibits superior dual resilience—maintaining higher growth in both downturns and booms. Simulation analyses further show that firms with weaker resilience quickly lose competitive ground amid economic volatility, whereas resilient firms successfully consolidate market share. We thus conduct a Minimum Resilience Threshold Analysis to determine critical resilience levels necessary for firms to maintain competitive parity under macroeconomic uncertainty.

52 - Influencing Travel Behavior Through Information: a Game Theory Perspective

Devin Rhoads, UConn Department of Civil & Environmental Engineering, Storrs, CT, United States

This research investigates how strategically designed information, guided by game theory, can influence individual travel behavior to enhance safety, efficiency, and equity across transportation systems. Rather than relying solely on infrastructure changes or financial incentives, this work explores how real-time and context-sensitive communication can shift behavior through perception and decision-making dynamics. Applications include detouring drivers to alleviate congestion, reducing station overcrowding in multimodal systems, and enhancing compliance with speed limits through strategically placed signage and feedback systems.

By modeling travelers as decision-makers in a shared system, game-theoretic frameworks help predict how users respond to different types of information. Concepts such as signaling, equilibrium strategy, and obedience constraints are applied to understand how messages delivered through digital displays, roadside signs, or in-app prompts can shape outcomes without coercion or financial incentives.

This project offers a novel lens on transportation planning: treating information itself similarly to infrastructure elements that shape collective mobility. The ultimate goal is to develop applicable strategies for transportation agencies to influence behavior at scale, reducing risks, optimizing flow, and promoting more equitable use of shared transportation networks.

53 - Using AI and Agent Based Modeling to Bridge Academic Findings and Organizational Practicality

Pierre Andrieux, Louisiana Tech University, Ruston, LA, United States, Justin Keeler, Jacob Whitmore

This study developed an AI based system that is designed to enhance agent-based modeling (ABM). In particular, it extracts static research findings and allows for making predictions as "what-if" scenarios. The intent was to advance simulation and replication techniques (e.g., Monte Carlo, ABM) to have greater dynamism. We calibrated this computational technique with published research that comprised of regression and difference testing of blue vs. white collar workers from Turkey. Constructs evaluated in the study included person-organization fit (POF) to predict affective/normative commitment, job satisfaction, organizational identification, and intentional to leave. The AI framework derived provides a pathway to address shortfalls in research, especially allowing for more practical usage rather than scholarly work sitting idle. Arguably, our work should cause researchers to pause and consider the idea of leveraging AI to bridge micro-level psychological mechanisms with macro-level organizational outcomes. In our calibration testing, the technique shows promise to advance ABM methodologically in organizational behavior research.

54 - Policy Gradient Optimization for Markov Decision Processes with Epistemic Uncertainty and General Loss Functions

Xiaoshuang Wang, Georgia Tech, Atlanta, GA, United States, Yifan Lin, Enlu Zhou

Motivated by many application problems, we consider Markov decision processes (MDPs) with a general loss function and unknown parameters. To mitigate the epistemic uncertainty associated with unknown parameters, we take a Bayesian approach to estimate the parameters from data and impose a coherent risk functional (with respect to the Bayesian posterior distribution) on the loss. Since this formulation usually does not satisfy the interchangeability principle, it does not admit Bellman equations and cannot be solved by approaches based on dynamic programming. Therefore, We propose a policy gradient optimization method, leveraging the dual representation of coherent risk measures and extending the envelope theorem to continuous cases. We then show the stationary analysis of the algorithm with a convergence rate of

$\mathcal{O}(T^{-(1/2)} + r^{-(1/2)})$, where T is the number of policy gradient iterations and r is the sample size of the gradient estimator. We further extend our algorithm to an episodic setting, and establish the global convergence of the extended algorithm and provide bounds on the number of iterations needed to achieve an error bound $\mathcal{O}(\epsilon)$ in each episode.

55 - Reframing Airport Choice in Platform Logistics: the Case of Amazon Air

Xiaofu Fan, Purdue University, West Lafayette, IN, United States, Karanki Fecri, Chien-Tsung Lu

While the substantial growth of e-commerce has elevated the role of air cargo from a peripheral service to a critical revenue source within the air transportation industry, airports, as essential nodes in this network, have increasingly benefited from this shift. In particular, the emergence of new players such as Amazon Air has significantly influenced the revenue growth trajectories of many airports. Despite this trend, the determinants guiding Amazon's airport selection strategy remain poorly understood. By analyzing data from 62 U.S. airports between 2010 and 2023, this study employs a Instrumental Variables Probit model to shed light on the key factors that influence Amazon's airport choices, thereby providing insights to help airports better align with the operational needs of major e-commerce carriers. The results reveal that Amazon prefers to choose airports that are non-hub, have good freight infrastructure, are far from urban centers, have low ground delays, and have a large scale of regional employment, while the per capita income has no significant level. These findings indicate the core logic of the "decentralized" layout of e-commerce logistics: by avoiding the high cost and congestion of traditional hubs, relying on professional facilities and flexible scheduling to achieve efficient performance, which confirms its high sensitivity to operational efficiency and scheduling freedom.

56 - Hierarchical Planning with LLM Agents for Simulating EV Charging Behaviors Under Demand Response

Yi Ju, University of California, Berkeley, Berkeley, CA, United States, Lunlong Li, Jingchun Wang, Jinhua Zhao, Scott Moura

With the rapid global adoption of electric vehicles (EVs), unmanaged charging poses serious risks to the power grid by exacerbating demand imbalances with renewables and overloading distribution infrastructure. Conversely, coordinated EV charging could transform millions of vehicles into a distributed, virtual energy storage system, rivaling the total capacity of today's utility-scale batteries. Realizing this vision, however, hinges on effective mechanisms that align individual driver incentives with broader system benefits, without compromising personal mobility needs.

This study explores the use of large language model (LLM) agents to simulate individual EV charging behavior in response to demand response (DR) signals. We introduce a novel decision-making task grounded in realistic, microscopic mobility trajectories and geolocated charging infrastructure. The LLM agent is given a detailed

two-day activity schedule together with tools to query charging station availability and pricing. It must then generate executable plans on when, where, and how to charge accounting for feasibility constraints, diverse pricing schemes, and its assigned persona. The task presents a combinatorially large solution space, requiring the agent to perform careful calculation and forward-looking reasoning to balance multiple objectives such as cost, time, uncertainty, behavioral inertia, and social norms. Leveraging a hierarchical planning workflow based on the ReAct and Reflexion paradigms, the LLM agent demonstrates plausible planning capability. This first-of-its-kind experiment offers a new lens for modeling complex human behaviors in EV charging, which opens the door to more realistic large-scale simulations for energy-mobility systems to assess the effectiveness of demand flexibility programs.

57 - Advancing Multiple Regression-Based Resilience Predictions with Transfer Function Methods

Fatemeh Salbough, University of Massachusetts Dartmouth, Dartmouth, MA, United States, Priscila Silva, Lance Fiondella

This research introduces a more advanced time series modeling technique that incorporates transfer functions to enhance resilience model prediction. Unlike traditional statistical methods that struggle with flexibility and long-term dependency forecasting, this approach effectively tracks and predicts system performance changes when facing multiple shocks and stresses of varying intensity and duration.

The transfer function methodology provides a structured framework for planning resilience assessment tests tailored to specific disruptions while guiding efficient data collection. Though resilience engineering is domain-specific, this versatile approach can be applied across various fields.

To validate its effectiveness, the researchers compared the transfer function model with regression models using interaction terms, analyzing historical data on job losses during the 1980 U.S. recessions. The numerical results, evaluated through goodness of fit measures, demonstrate the transfer function model's superior predictive capabilities, offering a compelling alternative approach to resilience assessment.

58 - Ultra-High Dimensional Threshold Selection for Quantile Feature Screening with Fdr Error Rate Control: A Case Study on High Blood Pressure Analysis

Saidat Sanni, University of Texas at San Antonio, San Antonio, TX, United States, Yan Yu, Zhigen Zhao

Identifying important genetic risk factors for high blood pressure is paramount for targeted interventions and comprehensive management strategies for this prevalent health condition. With ultra-high dimensional genetic factors, feature screening plays a vital role in retaining the important risk factors and screening out the unimportant ones. However, its efficacy depends on selecting the appropriate threshold in different data contexts. We propose the novel Quantile Mirror (QM) approach for data-adaptive threshold selection with false discovery rate (FDR) control in quantile feature screening, where abnormally high blood pressure levels are of the most interest. The symmetric QM statistics enable the estimation of the FDR. Multiple data splitting is employed for result stability and different thresholds are allowed for different quantiles. While many of the retained high-blood-pressure-related genetic features are validated from medical literature, some new risk factors are preserved. Additionally, we introduce the Quantile Reflection via Data Splitting (QREDS) and the Hard Threshold with QREDS feature screening procedures. We show that our proposed procedures asymptotically control the FDR under suitable conditions. We further demonstrate the performance of the proposed methods through extensive numerical analysis and simulation studies.

59 - The Performance Effects of Franchisee Autonomy in Operational Decisions: Evidence from a Restaurant Franchise

Jaewoo LEE, University of South Carolina, Columbia, SC, United States, Keith Skowronski, Sean Handley

Franchise systems balance the benefits of standardization with the need for local adaptation. While most prior research has focused on customer-facing autonomy, we examine how franchisees' autonomy in three operational dimensions—supplier selection, internal process compliance, and product assortment—affects outlet-level quality and sales performance. Using detailed monthly panel data from 90 outlets of a Korean restaurant franchise (2021–2023), we find that sourcing from alternative suppliers negatively impacts quality performance. Deviations from standard recipes enhance quality but reduce sales. Similarly, narrowing the adoption of brand-standard items dampens sales without yielding quality benefits. Post hoc analyses reveal that franchisor audits can mitigate the quality risks of using alternative suppliers and that the direction of recipe deviations matters—overserving improves satisfaction but undermines sales, while underserving reduces sales without enhancing satisfaction. We also show that adopting official side dishes, rather than entrées, is more effective in driving sales growth. These findings advance the franchising literature by shifting the focus from granted or perceived autonomy to exercised autonomy and by uncovering its differential performance effects across operational domains. For managers, the results suggest the need for differentiated autonomy strategies that involve working with franchisees to align their autonomous decisions with what has proven effective for sales and quality at the outlet level. This study offers actionable insights for franchise system design, governance, and performance optimization.

60 - An Integrated Assignment, Scheduling and Routing Optimization Framework for Humanitarian Food Distribution: A Case Study of the Banco De Alimentos De Bogotá

Ahmad Torabzadeh, university at Buffalo, buffalo, NY, United States, Sabrina Casucci, Robert Dell, Gonzalo Mejia

Food insecurity continues to be a pressing global challenge, impacting millions of people worldwide. The Banco de Alimentos de Bogotá, a food bank in Colombia, serves as a crucial support system for approximately 500,000 individuals through a network of 500 partner agencies. This research tackles the complex operational challenge of distributing food donations efficiently while managing limited resources and ensuring equitable delivery workloads. We develop an integrated agency assignment and vehicle routing model tailored to the food bank's daily logistics operations over a one-month planning horizon.

We solve our model in two steps with little loss of optimality. First, an integer linear programming (ILP) model assigns agencies to specific delivery days, accounting for varying delivery frequencies and aiming to balance workload across days. Second, for each day, we solve a capacitated vehicle routing problem (VRP) with time windows, route duration limits, and homogeneous vehicle constraints that minimizes total routing costs while promoting fairness in workload distribution across the fleet.

While each food bank operates under unique logistical, geographic, and organizational constraints, our model offers a flexible and adaptable optimization framework that can be customized to fit different operational contexts. By iteratively integrating agency assignment and daily routing, the model captures real-world delivery constraints and improves efficiency in both scheduling and routing. This contributes to humanitarian logistics by providing a practical tool that can help food banks enhance their operational performance and better serve communities in need.

61 - Rethinking Multitasking: IT, Teams, and Temporal Simultaneity

Li Zhang, MICHIGAN STATE UNIVERSITY, East Lansing, MI, United States, Julie Ryan Wolf, Brian Pentland

Modern organizational work is characterized by multitasking through concurrent task execution and frequent task switching. Extant research has primarily conceptualized multitasking as an individual-level, time-varying behavior defined by temporal concurrency, so it tends to overlook the role of teams and the enabling power of information technology (IT) in multitasking. True simultaneity of task execution has been dismissed as a misnomer due to assumed human limitations. Our work shifts the focus from individual to team-level multitasking and examines how IT and team enable multitasking behavior in practice. We conceptualize multitasking as composed of three distinct forms: pure IT-enabled multitasking, pure socially enabled multitasking, and hybrid socio-technical multitasking. Using electronic health record (EHR) audit logs from the University of Rochester Medical Center (URMC), we examine the impact of different multitasking forms on task documentation burden (measured as team-EHR interaction time). Our study shows that a 10% increase in pure IT-enabled multitasking is associated with a 41% decrease in task documentation time and a 10% increase in hybrid socio-technical multitasking is associated with a 35% decrease in task documentation time. Endogeneity in the model is addressed using Heteroskedasticity-based IV-method. Our study contributes to the multitasking literature by conceptualizing multitasking as a team- and IT-enabled phenomenon grounded in temporal simultaneity. Our findings demonstrate that the multitasking affordances of IT—when effectively enacted—can improve worker well-being through reduced documentation burden. The findings offer practical implications for IT value, system design, and IT-training interventions aimed at enhancing multitasking efficacy in complex, high-tempo environments.

62 - Robust Hedging Strategies for Community Choice Aggregators: Managing Market Price Uncertainty

Manar Jaradat, State University of New York, Binghamton, Binghamton, NY, United States, Neha Patankar, James Himelick

Community Choice Aggregation (CCA) is an energy procurement model that empowers local governments to purchase electricity on behalf of retail customers, giving communities greater control over energy sourcing and the ability to prioritize cleaner, renewable options. The increasing integration of renewable energy and storage fundamentally reshapes risk management in electricity systems. While this combination enhances system flexibility and resilience, and reduces operational and financial risks, it also introduces new complexities in planning and operation. Traditional risk strategies often rely on fixed probability distributions and assumptions that may fail under high uncertainty in evolving energy markets. In contrast, robust optimization explicitly incorporates ambiguity in model parameters and worst-case scenarios, offering stronger protection against volatile market conditions. This research develops a robust hedging strategy to address market price uncertainty, specifically tailored to CCAs. By leveraging robust optimization techniques and adapting conventional capacity expansion models, we support the design of diversified energy portfolios that are both cost-effective and resilient to uncertain market conditions, aligning with the sustainability and affordability goals of CCAs. The study provides two key contributions: First, insights into how renewable energy and storage integration transform the effectiveness of traditional risk management strategies. Second, practical recommendations for CCAs to enhance resilience and cost efficiency through robust portfolio planning. These findings support more informed decision-making for local energy programs and contribute to the broader effort of transitioning to a reliable, low-carbon energy future.

63 - Course Scheduling at Florida Polytechnic Using Genetic Algorithms

Cindy Ceijas, Florida Polytechnic University, Lakeland, FL, United States, Alexander Joyce

School operations, such as the timetabling problem, become a difficult optimization model as school enrollment increases. Allocating resources such as educators, classrooms, and time slots, under criteria like course level and course sequencing, is an integer NP-hard problem. Genetic algorithms provide an alternative to traditional optimization techniques by simulating evolution and natural selection over the set of possible solutions. This poster examines the use of genetic algorithms to solve the timetabling problem for Florida Polytechnic University. Our analysis investigates different heuristics involving crossovers using multiple fitness indicators, and variable mutation strategies using different genetic algorithm parameters.

64 - Optimization Models for the Ada Paratransit Districting Problem

Yanshuo Sun, FAMU-FSU College of Engineering, Tallahassee, FL, United States, Chinonso Okorie, Shijie Chen

Small and medium-sized paratransit operators typically provide services within a centralized region. By contrast, larger operators often divide their service areas into multiple zones, each managed by an independent contractor. Although this zoning strategy offers benefits, such as improved vehicle on-time performance, the zonal boundaries pose significant barriers to inter-zonal passengers. Despite the wide adoption of the multi-zone structure in major U.S. metropolitan areas, there is a notable research gap in the literature: no rigorous quantitative methods exist to support those important paratransit districting decisions. To address this gap, we present two integer programming models to assist transit authorities in dividing a paratransit service region into two zones. The optimization objective is to minimize inter-zonal trip requests caused by the established boundary while ensuring some workload balance. As the first model serves motivational purposes and is a simplified version of the second, we thoroughly tested the latter model using both synthetic and real-world data. The promising results suggest that the designed model could significantly advance paratransit districting practices for major U.S. paratransit authorities.

65 - A Comparative Evaluation of Transformer and Mamba Models for Healthcare Time-Series Applications

Abigail Binder, Rochester Institute of Technology, Rochester, NY, United States, Nasibeh Azadeh-Fard

Transformers have become the de facto standard for sequence modeling, while Mamba—a newly proposed state-space model—offers a compelling alternative that remains largely underexplored. In this poster, we conduct a structured literature-based comparison of both architectures, evaluating them along three key dimensions: computational complexity, interpretability, and data efficiency. Drawing on studies in healthcare time-series (e.g., patient vital signs, length-of-stay forecasting), we identify which model characteristics align best with resource-constrained clinical settings.

66 - An MDP Model of Inventory Management Policies for Managing Drug Shortages in Hospital Pharmacies Under Uncertain Lead TIME Information

Noah Chicoine, Northeastern University, Boston, MA, United States, Jacqueline Griffin

According to the ASHP, there are hundreds of drug products currently on shortage across hospitals in the United States, and that number is increasing. With the prevalence of drug shortages, shortage management has become an ongoing practice at hospital pharmacies. Hospitals employ a number of strategies to mitigate shortages, including decreasing utilization in certain floors, encouraging use of substitutable products, and ordering alternative products. Additionally, pharmacies utilize “estimated release dates (ERDs)”, a form of lead time information from upstream suppliers, to determine which mitigation strategies may be best to implement with respect to costs and impact on patients. Research has shown that ERDs can be inaccurate and subject to change before shipments arrive at the hospital. To investigate how this uncertain lead time information effects optimal inventory management decisions, we developed an MDP model of pharmacy decision-making during a drug shortage. By including actions that mimic extending product utilization and switching to alternative medications, we test the effects of different system costs on optimal policies, showing how different types of products may require vastly different management strategies.

67 - Filling Gaps OR Replacing Creators? Strategic AIGC Adoption in Stock Content Platforms

Xiaoxiang Wang, Tsinghua University, Beijing, China, People's Republic of

AI-generated content (AIGC) allows consumers to create customized content, challenging stock content platforms whose revenues depend on licensing professional user-generated content (PUGC) to consumers. However, under the scaling law of AI training, large PUGC inventories are valuable assets for launching platform-owned AIGC. Introducing AIGC can fill gaps in existing contents and generates new revenue, but may also substitute for PUGC, risking creator exit. We develop a two-period game-theoretic model to explore whether a stock content platform should introduce AIGC trained on creator contents, and how should it adjust revenue shares with creators. Unlike prior work, our model uniquely captures the dependency of AIGC quality on PUGC training data volume and AIGC’s generalization capability. Our results show that AIGC adoption is always optimal for small markets, but for large markets, profitability hinges on AI learning rates exceeding a critical threshold. Contrary to common belief, adoption does not necessarily lead to lower revenue shares for creators—platforms may raise shares either to address initial UGC shortages (small markets) or to accelerate AI training (high learning rates). Welfare analysis reveals that AIGC adoption can either benefit or harm all stakeholders depending on market parameters. Our results provide strategic guidance for platform operators on balancing new AI technology adoption with creator ecosystem sustainability.

68 - Hierarchical Data Modeling: a Systematic Comparison of Statistical, Tree-Based, and Neural Network Approaches

Marzieh Amiri Shahbazi, Rochester Institute of Technology, Rochester, NY, 14623, NY, United States, Nasibeh Azadeh-Fard

Hierarchical data structures are common in healthcare and other domains, yet rigorous comparisons across distinct modeling paradigms remain limited. This study presents a systematic evaluation of three hierarchical approaches—statistical (Hierarchical Mixed Models), tree-based (Hierarchical Random Forest), and neural (Hierarchical Neural Networks)—to model nested healthcare data. Using the 2019 National Inpatient Sample comprising over 7 million records from 4,568 hospitals across four U.S. regions, models were assessed in predicting length of stay (LOS) across patient, hospital, and regional levels. A comprehensive evaluation framework integrated both performance metrics and structural analysis. Model robustness was tested across different sample sizes, simplified hierarchies, and a separate intensive care dataset (MIMIC-IV). The tree-based approach consistently outperformed others in predictive accuracy, variance explanation, and stability, while maintaining computational efficiency. Neural networks captured mid-level structure more effectively but required greater computational resources and exhibited systematic bias. Statistical models offered fast inference and interpretability but struggled with prediction accuracy at intermediate levels. These findings provide practical guidelines for selecting appropriate hierarchical modeling methods based on data scale, computational constraints, and the nature of nested structures. This work contributes a unified benchmark and highlights trade-offs in scalability, interpretability, and precision—guiding researchers and practitioners toward informed methodological choices in hierarchical learning tasks.

69 - Blockchain Implementation in Internet of Things (Iot) Based Sustainable Supply Chain: Development a Framework Using Fuzzy Entropy-Waspas

Atefeh Shoomal, University of Texas at Arlington, Arlington, TX, United States, Mohammad Jahanbakht, Paul Componation, Paul Componation

The deployment of Internet of Things (IoT) and blockchain technologies plays a critical role in enhancing efficiency, resilience, and sustainability in supply chains. Despite their potential, adoption challenges complicate strategic decision-making. Selecting the optimal blockchain-IoT integration use case mitigates business risks, yet this decision is complex and influenced by multiple criteria. This study identifies key factors affecting blockchain-IoT adoption in sustainable supply chains through a comprehensive literature review based on the Technology-Organization-Environment framework. We propose an Entropy-Weighted Aggregated Sum Product Assessment (WASPAS) framework under a q-rung orthopair fuzzy set to prioritize these criteria and evaluate blockchain-IoT use cases for implementation in sustainable supply chain. The model integrates expert preferences and is validated through a manufacturing supply chain case study. The result of case study shows technology maturity, sustainability, and investment cost as top ranked criteria and IoT tracking with blockchain as the optimal use case. Sensitivity and comparative analyses further demonstrate its robustness and effectiveness. By reducing uncertainty, this model empowers supply chain decision-makers to adopt blockchain-IoT solutions that enhance sustainability and operational efficiency.

Keywords: Blockchain; Internet of Things; Sustainable Supply Chain; Technology-Organization-Environment; Entropy-WASPAS; q-ROFSs

70 - Prediction of Road Accident Severity Using Multimodal Machine Learning and Large Language Models

Felipe Villa, Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

Traffic accident-severity prediction has historically treated numeric traffic signals and crash narratives as disjoint data silos. We introduce a multimodal pipeline that unifies minute-level flow measurements from Automatic Vehicle Identification sensors with contextual embeddings extracted by a large language model from 2.070 historical crash reports. Central to our formulation is Medical-Assistance-Required Accident (MARA), an ordinal target that bridges engineering and clinical priorities by explicitly encoding whether on-scene medical support will be needed.

Sensor features and text embeddings are fused through cross-modal attention and fed to a gradient-boosted classifier. The resulting model achieves 94.4 % accuracy, 94.6 % precision, and 94.5 % F1, exceeding the best unimodal baselines by ≥ 20 percentage points. Most notably, recall for non-severe accidents leaps from 58 % to 81 %, while MARA recall reaches 93 %, ensuring that events demanding urgent care are rarely overlooked.

To our knowledge, this is the first study to deliver real-time accident-severity forecasting at motorway scale via sensor-language fusion. By coupling the new MARA variable with large-language-model embeddings, the framework not only advances predictive performance but also supplies a directly actionable triage layer for traffic-control centres. These findings establish a new benchmark for multimodal safety analytics and demonstrate the transformative potential of integrating foundation-model semantics into intelligent transportation systems.

71 - From Formulation to Programs are LLMs Ready for Operation Research?

Guoyun Zhang, National University of Singapore, Singapore, Singapore

The integration of Large Language Models (LLMs) with optimization modeling offers a promising avenue for advancing decision-making in operations research (OR). Traditional optimization methods—such as linear programming, mixed integer programming, and simulation—depend heavily on domain expertise to translate real-world problems into solvable mathematical models. While solvers like Gurobi and COPT are powerful, expert input remains essential for defining objectives, constraints, and variables.

This research investigates the potential of LLMs, specifically the DeepSeek-R1 model, to bridge this formulation gap using natural language understanding and code generation. Although prior models like GPT-4, Claude, and Bard have shown strong performance in NLP and reasoning tasks, their high token costs and tendency toward hallucinations limit real-world applicability in supply chain contexts. In contrast, DeepSeek-R1, a cost-efficient and high-performing model trained with reinforcement learning, presents a viable alternative. Despite its success in benchmarks such as LiveCodeBench and Math-500, its effectiveness in applied OR scenarios remains under explored.

This study systematically evaluates DeepSeek-R1 across four key OR benchmarks: NL4OPT, IndustryOR, EasyLP, and ComplexOR. Our methodology includes baseline assessments, the development of a hallucination taxonomy, and the application of mitigation strategies like LLM-as-a-Judge, Few-shot Learning (FSL), Tool Calling, and a Multi-agent Framework. These techniques aim to reduce hallucinations, enhance formulation accuracy, and better align model outputs with user intent.

72 - Optimal Targeted Intercity Travel Restriction Policies

Liam Ouyang, The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Xu OUYANG, Sai-ho Chung, Tsan-Ming Choi

As an effective non-pharmaceutical tool, travel restrictions are often adopted to contain the early spread of severe infectious diseases (e.g., SARS, COVID-19, and monkeypox). This study examines targeted intercity travel restriction policies to hedge against potential pandemic deterioration. We consider the correlation of disease spread among cities in deteriorating scenarios, modeled by distributionally robust optimization (DRO). The problem is formulated by a nonlinear huge-scale DRO model and then reduced to a mixed-integer linear equivalence of moderate scales. We develop a Benders decomposition algorithm, utilizing a special relation between master- and sub-problem variables. Experiments show our model “mean-variance dominates” a classic robust optimization model that ignores correlation of spread, in terms of higher pandemic control performance and lower performance variation. In the case study, targeted policies exhibit two to five times the pandemic control performance (i.e., infection reduced or human lives saved) against uniform travel restriction policies adopted in the real world. Policymakers are advised to impose targeted intercity travel restrictions as early as possible, since pandemic control performance is more obvious at the early outbreak stage. Targeted restriction policies are promising for developing countries because of comparable pandemic control performance under limited budgets, compared with those with adequate budgets.

1 - DecisionOPS in the Analytics Process: Collaboration, Observability, Testing, Ecosystem, and Workflows

Carolyn Mooney, Nextmv, Philadelphia, PA, United States, Tiffany Bogich

Optimization is founded upon the promise of efficiency and improving solutions. In today’s analytics environment, the leading data science and optimization teams will be defined by how they apply DecisionOps practices to test, deploy, and operate these solutions alongside software and business stakeholders. Join this session to learn basic concepts, real-world applications, and how to get started with DecisionOps in Nextmv, a platform for accelerating decision model development. This session is relevant to anyone working with tools such as: OR-Tools, Pyomo, HiGHS, VROOM, Gurobi, AMPL, FICO Xpress, Hexaly, Jupyter Notebooks, Statsmodels, Prophet, scikit-learn, Databricks, Snowflake, and more.

2 - Computing Dual Bounds of Set-Based Models Using Column Generation and Column Elimination in Hexaly

Julien Darlay, Hexaly, Brooklyn, NY, United States

Hexaly is a model-and-run solver that integrates heuristics and exact methods. A set-based modeling formalism was introduced to simplify the modeling of some combinatorial problems, like routing or packing problems. For instance, in a routing problem, list variables can be used to model the sequence of visits made by each truck. These decision variables are well suited for a heuristic search but are much more challenging to integrate into a mathematical programming approach to compute

lower bounds. A direct MILP reformulation introduces a quadratic number of binary decisions with several big M constraints, leading to poor scalability and bounds. Hexaly automatically detects such structures in a user model and reformulates them in an extended MILP model to compute lower bounds parallel to a heuristic search. This model is solved efficiently using the literature's state-of-the-art branch-and-cut-and-price techniques and column elimination algorithms. This talk will present the general approach, the algorithms used for the resolution, and some benchmarks on the classical vehicle routing and packing problems.

Group Decision and Negotiation

Chair: Danielle Costa Morais, Universidade Federal de Pernambuco, Recife, N/A, Brazil

1 - Behavioral Asymmetry in the Newsvendor Problem: a Fuzzy Prospect Theory Approach

WenYi Lee, National Taipei University of Business, Taipei, Taiwan, Yu-Rong Chen

The newsvendor problem is a foundational model in inventory and revenue management, traditionally assuming rational decision-making and risk-neutral preferences. However, real-world decisions often reflect asymmetric psychological responses to overordering and underordering. This study addresses this behavioral complexity by applying fuzzy prospect theory to the newsvendor framework. Our model integrates fuzzy logic to capture ambiguity in human perception and prospect theory to reflect loss aversion and reference dependence in inventory decisions. By accounting for the cognitive differences in how decision-makers perceive surplus versus shortage, our approach offers a more realistic understanding of inventory behavior under uncertainty. Numerical experiments demonstrate that incorporating behavioral asymmetry can significantly alter inventory strategies, with implications for more nuanced revenue management practices.

2 - Carbon Emission Reduction in Manufacture-Circulation Industrial System: An Assortment Optimization Embedded Cooperative Game Theory Method

Xihua Liu, National Frontiers Science Center for Industrial Intelligence and Systems Optimization, Northeastern University, China, Shenyang, China, People's Republic of, Shengnan Zhao, Lixin Tang

In recent years, significant carbon emission from human activity has led to global climate change, and many countries have begun to take measures to address this severe situation. In 2020, China proposed the goal of carbon peak and neutrality, which aims to peak carbon emission before 2030 and achieve the balance between carbon emission and absorption by 2060. In response to this, it is necessary for vertically aligned firms to collaborate to integrate resources and reduce repetitive production. This study focuses on the cooperation between firms producing steel, components and vehicles. A cooperative game theory model is adopted. Firms within the same product category can form coalitions to share their technology and jointly undertake the cost of production and carbon emission. The value of characteristic functions is determined by an assortment optimization model, where firm coalitions can choose a subset of the products they can produce to exhibit downstream firms. The objective is to minimize the total cost of the firm coalition. We employ a row generation framework: Solve the assortment optimization problem to obtain the characteristic function values of certain coalitions, and use row generation to tackle with the computational difficulty caused by the exponential number of possible coalitions. Different methods are used to allocate the total cost of a coalition to its members in a comparative way. Numerical experiments show that the formation of coalitions between firms reduces total carbon emission when compared with the non-cooperative scenario. The results provide insights for low-carbon collaborative production management between firms.

1 - Evolutionary Model of Data Market

Kewei Cai, Beihang University, Beijing, China, People's Republic of, Junhuan Zhang

The rapid expansion of data markets has garnered increasing scholarly and industry interest. We propose an evolutionary model of a data market microstructure including consumers, producers, and data platforms. Data platforms act as intermediaries, offering consumer data services and digital advertising services to facilitate product transactions. They collect consumption data from consumers and reveal it to help producers make informed decisions. Likewise, producers can advertise their products through these platforms. Consumers decide whether to share their data, while producers choose whether to advertise. Data platforms determine if they will provide data services. By examining the evolutionary strategies of each participant, we identify the equilibrium where all participants actively engage in the data market. This equilibrium is stable under certain pricing conditions and is influenced by several key factors: 1) Data platforms must balance pricing conditions between consumer data and digital advertising services, ensuring prices cover the opportunity costs of all participants. 2) Consumers' willingness to share data depends on privacy loss, search

cost, and compensation fees. 3) Producers' willingness to advertise is influenced by production cost, service costs, advertising impact, and product price. 4) Data platforms' willingness to provide services depends on data production cost, collection cost, and service costs. Also, we extend the model by incorporating dynamic incentives, pricing structures, and personalized advertising to enhance data sharing and advertising willingness. This study provides insights into data asset pricing and data market design.

2 - The Effect of Selling Asset Behavior on Investors' Returns: Analysis Using Data from Robo-Advisor Users

Norio Hibiki, Keio University, Yokohama, Japan, Yusuke Ushijima

Long-term investment and diversification are crucial for individual investors who employ asset management strategies using mutual funds and robo-advisors. However, some investors sell or withdraw funds for various reasons. These trading behaviors affect actual investor returns. Morningstar (2024) has demonstrated the investor gap between the total return of funds and the investor return, which is caused by trading behavior. Barber and Odean (2000) analyzed individual trading data and showed that frequent trading leads to lower performance, which has an unfavorable effect on asset growth. Therefore, this study focuses on investors' withdrawal behavior and analyzes the difference in investor returns and the relationship between them. We analyze transaction records (data) from approximately 380 thousand users of WealthNavi, a robo-advisor service provided in Japan. While results vary depending on the evaluation period, we find that users who do not sell their portfolio and invest over a longer period tend to have higher investment returns, on average, than those who have sold their portfolio. A regression analysis was conducted with the investor return as the dependent variable, a dummy variable representing selling asset behavior as the independent variable, and dummy variables for investment experience, additional deposits, investment dates, and valuation dates as control variables related to investor returns. The results showed that the selling asset behavior has a statistically significant negative correlation with investors' returns.

3 - Post COVID-19 Impact on Remote Work on the Housing and Commercial Real Estate

Victor Dichi, University of Miami, Miami, FL, United States, VINCENT OMACHONU

Since the onset of COVID-19, the amount of employed people working from home in the United States rose from 5.7% in 2019 to a staggering 17.9% in 2021 (Espitia et. al 2021, US Census Bureau 2022, Laura Pop-Badiu et. al 2024). As a result, the use of office space has declined dramatically, and the amount of office space still on the market, as well as the offices currently being built are not necessarily optimal. Due to this surplus of offices, the demand for office space has decreased, causing there to be a decrease in the efficiency of the office market. People now need more housing and housing space for their work, as people now need more space in their homes to work. Consequently, vacancy rates in the housing market have decreased, causing an incredible increase in housing demand, therefore creating a shortage in the market (Guirguis et. al 2023). The purpose of this research is to analyze the economic impact of remote work on the use of office buildings as well as housing real estate in major cities in the United States. Additionally, the study seeks to propose a way to stabilize this crisis through the use of economics and mathematical approaches.

4 - Incorporating News Headline Sentiment into the Markowitz Portfolio Selection Model

Joomi Park, Yonsei University, Seoul, Korea, Republic of, Seongmoon Kim

This paper proposes a method to enhance Markowitz's mean-variance portfolio model by incorporating sentiment indexes derived from news headline data. Specifically, the model adjusts the portfolio weights of individual stocks based on the results of sentiment analysis. The sentiment data were collected from the headlines of ten major Korean economic newspapers. To evaluate the effectiveness of the proposed model, we conducted a backtest using historical monthly stock return data from the South Korean stock market over a ten-year period, from March 2015 to February 2025.

Ambassadors Program

Chair: Banafsheh Behzad, California State University, Long Beach, Long Beach, CA, United States

1 - Well Informed: Increasing Wellness Capacity and Community Within Academia

Jessye Talley, Morgan State University, Baltimore, MD, United States

The Well INFORMED Mentorship Program provides space for faculty and PhD students to take a holistic approach to their academic experience. By understanding the intersection between their values, identity, and wellness they able to make connections that can inform their academic life. This talk will highlight the nuances and outcomes of this program.

2 - Levering the INFORMS Annual Meeting Host City Rotation to Improve the Visibility of Orms Among Students at Puis: the Inform's Promise Scholars Program

Juan Martinez Mori, University of Colorado Denver, Denver, CO, United States

One of the challenges with making ORMS more accessible starts with its name: compared to other STEM fields, the terms "Operations Research" and "Management Science" are not particularly indicative of what they are all about. In this INFORMS Ambassadors project, we leverage the Annual Meeting host city rotation to perform targeted outreach at local primarily undergraduate institutions (PUIs) to involve students in the Annual Meeting and introduce them to career opportunities in ORMS.

3 - A Machine Learning Approach for Identifying Marginalized Subgroups of INFORMS Members and Participants

Matt Baucum, Oklahoma State University, Stillwater, OK, United States

In this project, we analyze previously-collected survey data of INFORMS members and non-members to better understand the professional and demographic characteristics of INFORMS, how such characteristics have changed over time, and how such characteristics contrast with similar professional and academic organizations. Importantly, we also conduct a machine learning-driven heterogeneity analysis to identify subgroups of individuals who report feeling marginalized or excluded through participation in INFORMS events, and investigate whether such experiences serve as a barrier to membership for academics or professionals.

Data come from two INFORMS surveys administered in 2022 (to INFORMS members) and 2024 (to members and non-members), with several thousand completed survey responses across both years. We use factor analysis to identify dimensional scales that reliably quantify members' overall satisfaction with INFORMS and satisfaction with INFORMS' inclusivity. We then employ interpretable machine learning techniques to identify subgroups of individuals who are particularly likely to report negative experiences with INFORMS, or particularly unlikely to place membership. We also combine such techniques with autoregressive analysis to assess whether particular groups experienced notable changes in INFORMS satisfaction or membership intention between the 2022 and 2024 surveys.

4 - Operations Research in Women's Health and Healthcare: a Scoping-Inspired Narrative Review and Roadmap for the Future

Rachel Stephenson, University of Toronto, Toronto, ON, Canada, Rachel Wong

Operations Research (OR) approaches have been applied to derive meaningful policy insights and effective solutions to a broad range of healthcare problems, but we believe that there is a gap in OR literature addressing issues that differently or disproportionately impact women's health and healthcare (hereafter referred to as "issues in women's health and healthcare" for brevity). As such, we are undertaking a project to identify this gap and promote a research agenda to close it. The project consists of three phases:

Phase 1: Perform a scoping-inspired review of literature on significant issues in women's health and healthcare studied and published in top OR journals over the past ~10 years.

Phase 2: Distribute a survey to experts in women's health and healthcare with the research gaps identified in Phase 1. Experts will be asked to prioritize research areas, identify specific subproblems within broad areas that may be solved using OR approaches, and identify any emerging issues that were excluded from the list provided.

Phase 3: The results from Phases 1 and 2 will be synthesized and disseminated in a survey to the OR community. Experts will be asked to describe how OR could be applied to solve these problems.

The primary outcome of this work will be the identification of opportunities for novel applications of OR in women's health and healthcare. The goal of this project is to promote applications of OR to women's health and healthcare issues, and therefore, to ultimately improve women's health outcomes.

5 - Driving Engagement with Data: a Predictive Analytics Challenge for Community Impact

Imtiaz Ahmed, West Virginia University, Morgantown, WV, United States, Nathan Gaw

This project launched a student-driven predictive analytics challenge using INFORMS member survey data to uncover insights into stakeholder engagement, satisfaction, and participation. By identifying key drivers of retention and spotlighting underserved segments, the initiative generated actionable recommendations to strengthen mentorship, accessibility, and industry-academic collaboration. In parallel, a panel on algorithmic fairness invited dialogue on ethical model design and bias mitigation. Together, the challenge and discussion fostered community engagement while empowering the next generation of analytics talent to contribute to a more inclusive and data-informed INFORMS future.

6 - Sustaining Momentum: Advancing the INFORMS K-12 Education Outreach and Networking Program

Fenglian Pan, University of Arizona, Tucson, AZ, United States, Ken Murphy

This flash talk highlights the power of cross-society collaboration within INFORMS to tackle complex, real-world challenges through shared expertise in operations research, analytics, and data science. By bridging academic, industry, and educational communities—including outreach to K–12—we amplify our impact and inspire the next generation of problem-solvers. Whether optimizing supply chains or designing equitable public systems, our collective efforts demonstrate how interdisciplinary teamwork drives innovation and societal benefit.

7 - Understanding INFORMS Membership Dynamics and Trends from 2022-2024

Bing Si, Arizona State University, Tempe, AZ, United States, Alec Fishbach, Bo Li, Daniel Scott

Expanding participation amongst different member groups is essential to building a more inclusive professional community. In alignment with INFORMS' commitment to supporting a broad range of perspectives and backgrounds, this project proposes a data-driven initiative to analyze membership dynamics and trends from 2022 to 2024. Using survey data, the project seeks to uncover underlying organizational challenges and offer actionable strategies to improve member retention and reduce attrition across various member groups. By applying advanced analytics to INFORMS survey data, the study aims to generate meaningful insights that reinforce INFORMS' efforts to cultivate a collaborative, dynamic, and well-rounded professional community.

8 - Creating Pathways of Belonging in Supply Chain Management and Business Analytics

Afrooz Moatari-Kazerouni, Widener University, Chester, PA, United States, Jeff Lolli

Ensuring accessible and equitable career pathways in Supply Chain Management (SCM) and Business Analytics (BA) is critical for nurturing innovation and improving organizational performance. Nevertheless, existing literature highlights continual barriers for underrepresented students, including limited exposure to career opportunities, lack of mentorship, and a diminished sense of belonging within these fields. This study investigates how structured industry engagement can enhance students' perceptions, interest, and confidence in pursuing SCM and BA education and careers.

A cohort of high school students who identified as first-generation and/or students of color participated in a one-day industry event at an area venue, which included engaging activities such as tours, mentorship roundtables, career panels, and data analytics challenges. Using a web-based survey administered during the event, data were collected on the students' prior knowledge, perceived barriers, career interests, and confidence levels before and after participation. Quantitative analysis suggested that structured exposure programs not only increase awareness but also cultivate a stronger sense of belonging, which literature identifies as a key predictor of academic persistence and career attainment. This research offers evidence-based recommendations for designing outreach initiatives that effectively support underrepresented students in developing sustainable interest and engagement in SCM and BA, as well as ways to educate them on the vast and lucrative career paths available for post-secondary graduates in SCM and BA fields.

9 - Fostering Inclusive and Equitable Teaching and Learning Environments in Data Science and OR/MS Classrooms

Ying Lin, University of Houston, Houston, TX, United States, Yeawon Yoo, Woody Zhu

This project aimed to promote more inclusive and equitable teaching and learning environments in data science and OR/MS classrooms through three main activities. First, we hosted a webinar on culturally responsive instruction, where the guest speaker discussed core practices of culturally relevant pedagogy and how they can be meaningfully applied in data-centric courses. The session also addressed different entry points for implementing these approaches, common pitfalls to avoid, and strategies for self-reflection—emphasizing that culturally responsive teaching is an ongoing journey rather than a fixed goal. Second, we hosted the INFORMS Data Mining Society Teaching Award to recognize exemplary educators who applied innovative and inclusive strategies in data science and OR/MS instruction. Lastly, we conducted interviews with instructors and students with disabilities to better understand the barriers they face and identify practical solutions to improve accessibility and engagement in technical classrooms.

1 - The Effect of Generative AI-Generated Introductions on Early Fundraising Outcomes in Medical Crowdfunding

Wen Zhang, Baylor University, Waco, TX, United States, Yue Tang, Ruomeng Cui, Guihua Wang

In this study, we investigate the effect of using generative AI on early fundraising outcomes for medical crowdfunding campaigns. Using a dataset of medical-related campaigns from a leading crowdfunding platform, we analyze the effect of AI-generated campaign introductions on campaign donations in the first month after launch. Our results show that using AI-generated introductions can increase the total donation amount by 8.32% in the first month. Additionally, we find using AI-generated introductions can increase the total number of donations by 9.07% in the first month.

2 - Reducing No-Shows, Improving Continuity: The Combined Impact of Patient Interventions and Telehealth on Healthcare Utilization

Jiajia Qu, James Madison University, Harrisonburg, VA, United States

This study examines how patient intervention programs and telehealth services jointly influence healthcare appointment adherence and follow-up care patterns. Using patient medical history from a Northeastern U.S. healthcare system, we employ a robust analytical framework combining mixed-effects modeling to account for individual patient variability, difference-in-differences to assess program impacts, and propensity score matching to address selection bias. Our analysis evaluates both the

independent and synergistic effects of these interventions, with particular attention to their role in mitigating disparities across demographic and geographic groups. The findings provide critical insights for designing integrated care delivery systems that optimize access, continuity, and equity in healthcare utilization.

3 - The Effect of Platform Intervention Policies on AI Transparency: An Empirical Investigation of AI Labeling and User Engagement

Qinhui Wang, Oklahoma State University, Stillwater, OK, United States

The rapid proliferation of AI-generated content (AIGC) on digital platforms—particularly deepfakes involving synthetic images, audio, and videos—has intensified concerns about misinformation, content authenticity, and user trust. Social media users can now effortlessly generate and disseminate hyper-realistic synthetic media, which may obscure authentic content and facilitate malicious manipulation. In response, major platforms have implemented AI labeling policies to enhance transparency and mitigate the societal risks posed by deepfakes. This study empirically examines the effectiveness of such interventions by analyzing the relationship between AI label disclosure and user engagement, and how perceived video authenticity moderates this effect. Drawing on the Elaboration Likelihood Model (ELM), we theorize that AI labeling serves as a peripheral cue that negatively influences user engagement, particularly when content is flagged as synthetic. Moreover, we posit that higher levels of perceived authenticity may exacerbate this negative effect, as users become more sensitive to potential deception. To test these hypotheses, we analyzed a dataset of 809 TikTok videos containing 115,053 user comments, generated by 32 unique content creators between November 12, 2024, and April 14, 2025. The findings aim to inform policy and design strategies for platform governance in an era increasingly shaped by generative AI.

1 - A Novel Methodology for Sensitivity Analysis of Combinatorial Optimization Using Predictive Modeling

Nishit Bhavsar, McMaster University , Hamilton, ON, Canada, Elkafi Hassini, Manish Verma

Mixed Integer Programming (MIP) is widely used for real-world applications such as resource allocation and network scheduling. However, its reliance on deterministic parameters limits its ability to generate long-term, reliable solutions. While stochastic and robust optimization address parameter variability, we propose a novel approach that integrates optimization and predictive analytics to enhance solution reliability. Our methodology involves three steps: (1) solving the MIP for multiple instances with varying deterministic parameters, (2) compiling optimization results into a database, and (3) training a predictive model to uncover patterns. We apply this to a MIP optimizing rail-truck intermodal networks for hazardous materials shipments, minimizing transportation costs and risks. The model determines intermodal routes, terminal selection, train connections, and drayage routes using realistic Canadian and U.S. networks. This approach improves MIP reliability by leveraging predictive insights, offering a more practical decision-making tool for complex transportation networks.

2 - Data-Driven Decision-Making in Healthcare Access Modeling: a Comparative Framework Analysis

Yujia Xie, Georgia Tech, Atlanta, GA, United States

Effective policymaking in healthcare access requires modeling that captures dynamics between healthcare supply and demand, further identifying opportunities to address barriers to receive adequate care. However, the uncertainty in the input data, the patient-provider interactions, the various system constraints, and the proper measurement for assessing access adequacy, all pose challenges in modeling and its use in decision making.

This presentation features two distinct modeling frameworks—simulation and optimization—applied to model healthcare access. Each demonstrates unique methodological challenges, spanning from data acquisition and input modeling to model design choices. The comparison between the two mathematical modeling approaches will highlight the different types of evaluations and the distinct policy insights each model can provide. For example, an optimization model can effectively optimize for a targeted performance measure, providing an optimal view of access, suitable for high-level (e.g., population level) insights. In contrast, a simulation model offers more granular statistics, providing a more realistic assessment of system behavior, especially under input uncertainty, however it lacks the efficiency of direct optimization for specific measures.

Acknowledging these unique input requirements, modeling strengths, and evaluation considerations is crucial for effective data-driven decision-making. This presentation illustrates the comparisons over a practical application focused on evaluating access to pediatric psychosocial services within a Medicaid-insured population.

3 - Scalable Linear Programming Based Optimization Algorithms for Data Science Applications

Yakun Wang, Lehigh University, Bethlehem, PA, United States

Many problems in data science—such as inference in graphical models and clustering—lead to mixed-integer nonlinear optimization problems that are computationally intractable. Existing methods often rely on heuristics with limited optimality guarantees. In this talk, I will present a line of research focused on developing strong linear programming (LP) relaxations that enable principled and scalable global optimization for these challenging problems.

In the first part, I address the inference problem in higher-order undirected graphical models. We reformulate the problem as a binary polynomial optimization and propose several LP relaxations. Applied to two applications—image denoising and error-correcting code decoding—our approach demonstrates that the LP relaxation is nearly always tight for image denoising and significantly outperforms existing LP-based methods in the decoding tasks.

In the second part, I focus on clustering. Building on a strong LP relaxation for the K-means clustering problem, we develop a scalable algorithmic framework for global optimization. This framework includes a separation algorithm for cutting-planes and leverages GPU-accelerated first-order solvers for LP to handle large-scale instances. To demonstrate the framework's flexibility, we incorporate several fairness notions from the literature for K-means clustering and extend the approach to spectral clustering. Extensive numerical experiments demonstrate that our framework can solve K-means problems to global optimality for datasets with up to 4,000 points, with promising applications in social network analysis and fairness-aware machine learning.

4 - On Feature Learning in Layered Models: An Optimization Perspective

Yunlu Chen, Northwestern University, Evanston, IL, United States

Layered models, such as neural networks, extract meaningful features through empirical risk minimization, yet the principles behind this process remain unclear. We analyze a two-layer nonparametric regression model akin to neural networks and prove that it naturally induces dimensionality reduction by identifying feature subspaces relevant for prediction—without explicit regularization. Our results explain this implicit regularization through set identifiability in optimization, showing how "sharpness" in the optimization landscape naturally enforces low-complexity solutions in finite samples.

Technology Strategy for Managers and Policymakers

Invited Session

Information Systems

Chair: Naveen Thotadamane Basavaraj, Indiana University, Bargsersville, IN, United States

1 - Betting on Crime? the Impact of Legal spORts Gambling on Criminal Activity in the U.S

Kailing Mao, Carnegie Mellon University, Pittsburgh, PA, United States

The rapid expansion of legalized sports gambling has introduced significant societal problems that extend beyond individual financial consequences to broader social outcomes. Although previous research has linked sports betting to problem gambling, financial distress, and mental health concerns, its second-order effects remain underexplored. This paper examines the impact of widespread sports gambling on property crimes, particularly with the addition of an online channel. Furthermore, we also found young men are more likely to commit these crimes compared to their female counterparts, post-relative to pre-legalizing sports betting. The findings contribute to the growing discourse on the unintended social consequences of sports gambling and iGambling, emphasizing the need for regulatory measures to mitigate its broader societal impact.

2 - Clean up Your Act: the Regulation of Sexually Suggestive Live-Streaming Content

Yuan Yuan, Carnegie Mellon University, Pittsburgh, PA, United States

As live-streaming becomes increasingly prominent, how influencers present themselves to the public in real time has become central to online interactions. One controversial but unexplored behavior in this space is the use of private information, especially sexually suggestive content, to attract viewers. We leverage rich data from Douyu.com—a leading Chinese live-streaming platform, including audience activity logs, video content, and a platform-wide policy banning such content—to provide a comprehensive analysis of its prevalence, impact, and regulation. Using multi-modal video analytics that integrate computer vision and language models, we extract and quantify sexually suggestive content and find it to be positively associated with higher audience engagement, highlighting economic incentives for influencers. We causally identify the effects of the policy shock—the ban on sexually suggestive content on Douyu platform—and show that it caused significant declines in both audience engagement (demand) and content production (supply), highlighting the economic costs of content regulation. The decline is particularly pronounced in appearance focused content categories where influencer appearance is central to the content. We develop a stylized game-theoretic model that surprisingly predicts that the impact of policy shock may not be universally negative. The policy reduces the supply of cheap (to produce) sexually suggestive content and causes some influencers to exit, thus lowering competition. This can incentivize a segment of influencers to invest more in content creation. Thus, the negative impact of content regulation can be offset for this segment of influencers.

3 - Information Integration and Hospital Performance: the Role of Managerial Ability

Tianjian Guo, Indiana University, Indianapolis, IN, United States

Alternative payment models (APMs) have emerged as a key strategy for improving care quality while ensuring financial sustainability in the U.S. This paper examines how two organizational capabilities—managerial ability (MA) and information integration capability (IIC)—jointly influence hospital APM adoption and operating margin. Grounded in the resource-based view and dynamic capability theory, we hypothesize that hospital-level MA, IIC, and their interaction positively affect both outcomes. Using a panel dataset of over 18,000 hospital-year observations from 1,904 U.S. hospitals, we find that MA and IIC each have a positive effect on operating margins, and that their interaction has a complementary effect on both outcomes. Further analysis reveals that MA and IIC have distinct effects on the adoption of specific APM types with different levels of financial risk. These findings offer important policy and managerial implications, highlighting how hospitals can strategically leverage managerial and IT capabilities to adapt to the evolving healthcare landscape.

1 - Whose Ideas Advance? Power, Status, and Decision-Making in Human and AI Design Teams

Yakira Mirabito, Massachusetts Institute of Technology, Cambridge, MA, United States

Design decisions in engineering are shaped not only by technical considerations, but also by complex organizational dynamics. My research investigates how hierarchy, including power and status, affects the evaluation and selection of design ideas, and how these dynamics evolve as AI becomes more integrated into engineering work. This talk draws from three studies that investigate how team dynamics and AI tools influence decision-making in engineering contexts. First, an observational study of industry design reviews highlights how hierarchy affects whose feedback is considered. Building on these insights, I conducted controlled experiments that manipulated participants' sense of power and status to examine how these factors shape design evaluations. A follow-up study extends this work by exploring how power dynamics affect the evaluation and selection of AI-generated versus human-generated design concepts. In this talk, I will briefly introduce the first two studies and focus on the third, which examines how power influences the evaluation and selection of AI-generated ideas. Together, these studies reveal how hierarchy and emerging technologies interact to influence design outcomes.

2 - Improving Human-AI Workflows for Clinical Decision-Making

Sarah Jabbour, University of Michigan, Ann Arbor, MI, United States

Accurate diagnosis is critical to the care of hospitalized patients, yet diagnostic errors remain common. While AI tools have the potential to support clinicians in making complex decisions, their real-world impact depends on how clinicians interact with them. Even high-performing models can mislead clinicians when deployed, especially in the presence of automation bias—where humans over-rely on AI even when it is wrong. Most models are optimized in isolation, without regard for how humans incorporate predictions into their decision-making. To address this, we conducted two large-scale randomized clinical vignette studies evaluating two automation bias mitigation strategies: instance-based image explanations and selective prediction. We found that image explanations do not help clinicians recover from inaccurate AI, while selective prediction does reduce automation bias—but at the cost of increased false negatives, potentially leading to missed diagnoses. These findings highlight the need for human-centered evaluation frameworks that explicitly account for clinician-AI interaction.

3 - Accuracy Obsession: Humans Prioritize Immaterial AI Accuracy over Their Own Compensation Unless We Educate Them

Matthew DosSantos DiSorbo, Harvard Business School, Boston, MA, United States, Kris Johnson Ferreira

Problem Definition: Accuracy isn't everything. Often high or low sensitivity is more important than overall correctness — however, we find that humans prefer accurate algorithms, even to their detriment. We identify and address an accuracy obsession: humans trust algorithms based on the algorithm's accuracy, not the actual monetary reward they could earn by using the algorithm.

Methodology/results: We model a two-stage algorithm that estimates the probability of a positive case and, if that probability exceeds a pre-determined threshold, recommends a human review; the human then makes the final decision. Penalties and rewards incurred by the human vary across outcomes. However, we introduce theory suggesting humans have an accuracy obsession: trust in the algorithm's recommendations is determined by algorithm accuracy, not performance (reward earned by following the algorithm's recommendations). Online lab experiments confirm our hypotheses: participants trusted a sub-optimal algorithm calibrated to maximize accuracy, not reward, much more than an optimal algorithm calibrated to maximize reward. These results held across two contrasting settings: high and low penalty for false negatives and, in turn, an optimal algorithm that is much more, and much less, sensitive than the sub-optimal algorithm. Finally, we design an educational intervention that mitigates the accuracy obsession.

Managerial Implications: We demonstrate that humans are biased towards accuracy obsession: trusting algorithms based on their accuracy, not their expected reward. We introduce a simple educational intervention that mitigates this bias, and hope our work will help managers prepare their employees for success in the many human-AI collaborations where accuracy isn't everything.

4 - The AI Management Paradox: How Algorithmic Control Systems Drive Efficiency but Erode Consumer Trust

Qiaowen Guo, Washington University in St. Louis, St. Louis, MO, United States, Xiang Hui, Fuqiang Zhang, TIANJUN FENG

<p break-words="">Can AI management systems optimize workforce performance without sacrificing the human elements that build consumer trust? I investigate this paradox through a large-scale field experiment at a leading e-commerce platform, randomly assigning 265,967 customer service interactions to either algorithmically-managed gig workers or traditionally-supervised employees.

<p break-words="">The results reveal a stark efficiency-trust tradeoff. Algorithmic control excels at driving measurable performance: gig workers achieve 35% faster service, 4% higher case closure rates, and 30% quicker response times. However, these efficiency gains come at a profound cost to consumer trust. Customers served by algorithmically-managed workers express 7% more negative emotions and subsequently reduce their platform purchases.

<p break-words="">Using machine learning text analysis, I uncover the mechanism driving this paradox: AI's narrow metric focus creates exploitable loopholes that workers strategically game. Nearly half (47.4%) of gig workers' case transfers are unnecessary escalations designed to boost performance and compensation. These strategic behaviors don't just frustrate consumers—they fundamentally erode trust. Following strategic transfers, consumers shift purchases from high-value durable goods to low-cost consumables, a 9.65% reduction in average product price that signals diminished platform confidence.

<p break-words="">This research exposes a critical vulnerability in AI management systems: optimizing for measurable efficiency can systematically degrade unmeasurable trust. As millions of workers globally transition to algorithmic management, my findings provide essential insights for designing AI systems that balance operational efficiency with the human elements necessary for sustained consumer relationships. The future of workforce management depends on resolving this paradox.

Machine Learning and Optimization

Job Market Showcase

Job Market Showcase

Chair: Nathan Justin, University of Southern California, Los Angeles, CA, United States

1 - Interplay of Global Optimization and Machine Learning

Pariyakorn Maneekul, University of Washington, Seattle, WA, United States

High-dimensional black-box optimization is a prevalent challenge in science and engineering. Through the interplay between optimization and machine learning, we develop adaptive search algorithms that balance exploration, exploitation, and estimation by leveraging machine learning to construct efficient surrogate models. Three primary contributions are presented. First, a multi-level Partitioning and Branch-and-Bound (PBnB) algorithm is proposed for level-set approximation. This method enhances the original PBnB by using importance sampling to identify promising subregions and integrating Gaussian processes to guide local exploration, with theoretical bounds on the approximation quality.

Second, to address high dimensionality, the Branching Adaptive Surrogate Search Optimization (BASSO) framework is introduced. A finite-time analysis proves that BASSO can achieve performance that scales linearly with dimension under specific theoretical assumptions. Implementations using Gaussian process and regularized quadratic regression surrogates are explored to balance local exploitation with global exploration, and numerical experiments investigate the gap between theory and practice.

Finally, for noisy functions, the dissertation extends the Single Observation Search Algorithm (SOSA). It replaces neighborhood averaging with a more robust quadratic regression for function estimation and incorporates optimistic sampling from reinforcement learning to improve the search strategy. Theoretical convergence results for this enhanced SOSA are provided, and numerical experiments demonstrate significant performance gains over the baseline algorithm. This research culminates in a discussion of future applications, including the potential of quantum computing for global optimization

2 - Learning Optimal Prescriptive Trees Robust to Distribution Shifts

Nathan Justin, University of Southern California, Los Angeles, CA, United States, Daniël Vos, Phebe Vayanos

In domains such as personalized medicine, historical data is used to learn what treatments to prescribe to maximize positive outcomes. Previous studies have proposed methods for creating prescriptive trees: human-interpretable diagrams that indicate what type of treatment an individual should get based on their measurements. However, a remaining problem is that the models perform worse over time when there is a shift in the data collection process or when data from a different source is used during the training and prediction phases. To solve this problem, we propose a method that considers data uncertainty by optimizing distributionally robust prescriptive trees. We formulate a linear-time algorithm to find the worst-case distribution shift within a given Wasserstein distance around the dataset and use it as a subroutine within the main problem. Our algorithm does not depend on any specific causal effect estimator and can, therefore, be applied in various contexts.

3 - Scalable First-Order Method for Certifying Optimality in Interpretable Machine Learning

Jiachang Liu, Cornell University, Ithaca, NY, United States, Soroosh Shafiee, Andrea Lodi

For interpretable machine learning in high-stakes decision-making and scientific knowledge discovery, ℓ_0 optimization has emerged as a powerful technique. Unlike past approximation-based methods, it can yield extremely sparse models without compromising accuracy --- even in the presence of high-dimensional and highly correlated features. However, solving the ℓ_0 problem to optimality remains computationally challenging for large-scale datasets. A major bottleneck lies in the expensive computation of dual bounds in the branch-and-bound framework.

To address this, we develop a first-order proximal gradient method to solve the perspective relaxation of the original cardinality-constrained problem. We reformulate the relaxation as a composite optimization problem and show that the proximal operator of its non-smooth component can be computed exactly in log-linear time complexity, eliminating the need to solve an expensive second-order cone program. We further introduce simple restart strategies that achieve the optimal linear convergence rate while preserving low per-iteration computational cost. Lastly, we design our algorithm with GPU-compatibility in mind, as matrix-vector multiplication is the most computationally expensive step; this allows us to significantly accelerate our method using GPUs.

Extensive experiments on synthetic and real-world datasets demonstrate that our method significantly accelerates dual bound computations and is effective in providing optimality certificates for large-scale problems. Such a success opens doors to new research opportunities in developing GPU-friendly first-order methods in both machine learning and mixed-integer nonlinear programming.

High-dimensional Data Analysis II

Job Market Showcase

Job Market Showcase

Chair: Wuxia Chen, University of Pittsburgh, Pittsburgh, PA, 15224-2136, United States

1 - Tensor-Based Predictive Modeling and Control for High-Dimensional Streaming Data

Zihan Zhang, Georgia Institute of Technology, Atlanta, GA, United States

The rapid advancement of sensing technologies has led to an explosion of high-dimensional data—from high-resolution images and videos to 3D point clouds—that fundamentally challenge traditional control methodologies. Conventional approaches, rooted in low-dimensional signal processing, fail to capture the complex spatio-

temporal dependencies inherent in such data. Simple vectorization disrupts essential structural information, while many learning-based methods require extensive datasets and lack rigorous theoretical foundations.

This talk presents a suite of tensor-based process control frameworks that preserve spatio-temporal structure while enabling principled control analysis. I will introduce strategies for incomplete sensing scenarios, novel system modeling approaches that capture localized correlations, and dynamic controller optimization methods. The framework naturally extends to address nonlinear spatio-temporal correlations via diffusion models, while also providing uncertainty quantification capabilities.

These contributions establish a data-efficient, theoretically grounded paradigm for controlling modern intelligent systems operating with high-dimensional, multimodal sensory data.

2 - Adaptive Tensor and Multimodal Learning for Human-Centered Systems

Elif Konyar, Georgia Institute of Technology, Atlanta, GA, United States, Kamran Paynabar

Modern engineering and healthcare systems generate high-dimensional, multimodal, and distributed data that capture complex interactions between humans, machines, and environments. Leveraging these data requires methods that are privacy-preserving, interpretable, and robust to heterogeneity and irregularity. In this talk, adaptive tensor and multimodal learning methods will be presented that advance two complementary directions: human-centered systems, which use interpretable and privacy-preserving models to enhance decision-making in healthcare, manufacturing, and transportation; and human-in-the-loop systems, which directly incorporate human behaviors and expertise to enable adaptive, user-aware AI. The talk will cover federated tensor regression for decentralized telemonitoring and industrial fault detection, semi-supervised tensor decomposition for computational phenotyping from electronic health records, and robust tensor models for anomaly detection in manufacturing and transportation networks. It will also highlight multimodal modeling of gaze, head, and hand motion in augmented reality-guided tasks. Together, these contributions demonstrate how tensor and multimodal learning can support trustworthy, personalized, and adaptive human-AI systems.

3 - Directed Graphical Models for Root Cause Analysis in Multimodal Systems Collecting Heterogeneous Data

Manni Zhang, Purdue University, West Lafayette, IN, United States, Ana Estrada Gómez

Nowadays, complex systems are equipped with multiple sensors that collect high-dimensional and heterogeneous data, including scalars, functional signals or profiles, and images. Such systems are prone to failures, and diagnosis is hard as the intricate interactions among the variables mask the root causes for fault diagnosis. Directed graphical models (DGMs) are a powerful tool for representing the probabilistic relationships between variables in such systems. Nonetheless, frameworks learning DGMs with mixed types of data are scarce. Existing methods focus on either scalar variables or profile data, or have stringent assumptions. In this article, we propose a framework, tensorDGM, for all data types and learn the structure of the system for root-cause analysis. We learn the structure of the DGM by fitting penalized tensor-on-tensor regressions with group Lasso penalties for variable selection and an L2 penalty to handle the group selection of variables. To solve the optimization problem, we propose a cyclic coordinate accelerated proximal gradient descent algorithm with Bayesian optimization for hyperparameter tuning. Through simulations and a case study, we illustrate the advantages of the proposed method, tensorDGM.

Managing Disruptions

Job Market Showcase

Job Market Showcase

Chair: Ozoemenam Ohagwu, Walden University, 100 Washington Square, Minneapolis, MN, 55401, United States

1 - The Role of Firm Risk in Supply Chain Network Adaptation

Shailesh Divey, MIT, Cambridge, MA, United States

Problem Definition: This paper investigates the impact of a firm's financial risk on its position within a supply chain network. Given the increasing complexity of supply chains and the role of financial stability in shaping business partnerships, understanding these dynamics is crucial for both firms and policymakers. **Methodology/Results:** We analyze supplier-customer relationship data from the US manufacturing industry using network analysis techniques. Firm risk is measured through idiosyncratic volatility derived from the Fama-French three-factor model with industry effects asset pricing model, and supply chain centrality is captured using degree centrality and eigenvector centrality. Our study employs fixed effects regression models and dynamic panel estimation techniques to establish relationships between firm risk and network position. We show how a firm's centrality adapts to a change in its risk exposure. **Managerial Implications:** This study provides critical insights for managers and policymakers aiming to strengthen supply chain resilience. Firms must proactively manage financial risk to maintain strategic supplier and customer relationships. Monitoring network structures and implementing strategies like supplier diversification and credit risk management can mitigate adverse effects. Additionally, high-risk firms can explore contractual mechanisms or risk-sharing agreements to sustain strong supply chain ties. Academics studying supply chain adaptation and risk propagation can build upon these findings to further explore the intersection of financial stability and network resilience.

2 - Managing Supply Disruption Risk: Selecting Unreliable Suppliers Under Cardinality Constraints

Ning Ma, Arizona State University, Tempe, AZ, United States, Heng Zhang, Yimin Wang

Recent natural disasters have significantly heightened the risk of supply disruptions, underscoring the urgent need to improve our understanding of how to effectively configure supply bases to manage unreliable supplier yields. While the literature has extensively examined the trade-off between cost and reliability, it has largely overlooked constraints on the supplier base—particularly cardinality constraints that naturally reflects considerations of cost control, operational efficiency, and the development of stronger supplier relationships.

This study addresses this gap and enhances the existing body of knowledge regarding the optimal selection of suppliers within a supply base. We demonstrate that the prevailing approach of ranking suppliers based on cost and reliability is not universally applicable when the cardinality constraint is introduced. Moreover, we show that the supply base design problem does not exhibit desirable mathematical properties, such as submodularity, which presents significant challenges for its analytical treatment.

To overcome these challenges, we propose a uniform demand approximation (UDA) schedule, which promotes a surrogate optimization problem that approximates the original problem. We derive a fully polynomial-time approximation scheme (FPTAS) for this problem. Additionally, we prove that the surrogate problem exhibits the ordered-submodularity property, enabling the use of efficient greedy-type algorithms when the supplier base is subject to cardinality, knapsack, or matroid constraints. Through numerical studies, we demonstrate that our solution is highly efficient and outperforms all benchmarks. Furthermore, we provide managerial insights into the structure of the optimal supply base configuration.

3 - On the Pursuit of ESG and Firm Resilience

WENTING LI, Arizona State University, Tempe, AZ, United States

Problem Definition: Environmental, social, and governance (ESG) practices, while broadly adopted, are increasingly questioned for their value. Amid ongoing global disruptions, executives question whether ESG is a discretionary cost that harms firm performance or a source of strategic value. While extensive research exists on ESG and firm performance, empirical evidence disentangling its impact during crises, particularly within the supply chain context, remains scarce. **Methodology/Results:** Leveraging the COVID-19 pandemic as a natural experiment, we assess firms' competitiveness relative to industry peers amid crises. Our instrumental variable and matching estimations reveal that while ESG adoption has no significant effect on firm performance under stable market conditions, it becomes a key differentiator in crises. A standard deviation increase in ESG score leads to a 0.107 unit (1.9%) rise in excess return on assets (ROA) compared to industry peers. Moreover, our

mechanism analyses uncover two distinct pathways of this ESG-enabled competitiveness: (1) supplier-driven cost efficiencies and (2) buyer-driven ESG price premiums. We show that the cost efficiency pathway stands out as the primary source of competitive advantage during disruptions. In comparison, the ESG-driven price premiums pathway may be present during normal times but fades during disruptions. Managerial implications: Our study suggests that ESG adoption may not benefit firms during normal times but becomes crucial during disruptions when resources are scarce. With heightened global disruptions, our study offers compelling evidence for a paradigm shift in ESG investment from social responsibility to supply chain resilience.

4 - Effective Strategies to Mitigate the Impact of Cargo Shipment Abandonment

Ozoemenam Ohagwu, Walden University , Minneapolis, MN, United States

Business leaders in multiple U.S. exporters refuse to pay freight charges and abandon their cargo shipments, leaving shipping business leaders with monetary losses. Some small and medium-sized U.S.-based shippers lack effective strategies to address the risk of cargo shipment abandonments. Grounded in the theory of constraints, the purpose of this qualitative pragmatic inquiry study was to explore the effective strategies used by small and medium-sized U.S.-based shippers to successfully mitigate the risk of cargo shipment abandonment. The participants included three U.S. shipping industry leaders from non-vessel-operating common carriers and three from vessel-operating common carriers, all with an average of 25 years of experience and a demonstrated ability to effectively mitigate cargo shipment abandonment risks. Data were gathered through semistructured interviews and publicly accessible information. Through thematic analysis, eight key themes emerged: relationship management, disruptions, financial management, risk management and recovery, service quality, technology, unclaimed and abandoned cargo, and service category. A key recommendation is for U.S.-based shippers to employ effective communication and collaboration with stakeholders. The implications for positive social change include the potential for U.S.-based shippers to effectively manage maritime supply chain disruptions. This capability reduces cargo shipment abandonment and operational costs, leading to lower local and international commodity prices. Ultimately, it enhances community sustainability, creates new job opportunities, and ensures tax revenues that can bolster local financial stability.

Multi-Objective Optimization

Contributed Session

Contributed

Chair: Dhiraj Pokhrel, University of Tennessee, Knoxville, Knoxville, TN, United States

1 - Preference Optimization on Pareto Sets: on a Theory of Multi-Objective Optimization

Abhishek Roy, Texas A&M University, College Station, TX, United States, Geelon So, Yi-An Ma

In multi-objective optimization, a single decision vector must balance the trade-offs between many objectives. Solutions achieving an optimal trade-off are said to be Pareto optimal---these are decision vectors for which improving any one objective must come at a cost to another. Many decisions can be Pareto optimal, so when the decision maker can choose only one, this raises questions of which solution to pick and how. We formulate the problem as $\text{Pareto-constrained optimization}$, where the goal is to optimize a preference function constrained to a set of Pareto optimal solutions. This constrained optimization problem poses significant challenges: not only is the constraint set defined implicitly, but it is also generally non-convex and non-smooth, even when the objectives are strongly convex. We propose a reformulation of the problem where the constraint set is redefined in terms of an appropriately defined manifold. This reformulation allows us to introduce a clearer and more accurate notion of optimality and stationarity, improving upon existing definitions in the literature. We provide an algorithm with a last-iterate convergence rate of $O(K^{-1/2})$ to this notion of stationarity when the preference function is Lipschitz smooth and when the objective functions are strongly convex and Lipschitz smooth. Moreover, motivated by practical applications like Reinforcement Learning with Human Feedback (RLHF), we extend this algorithm to tackle the case where the preference function can only be queried via dueling feedback.

2 - On Presaging Multiple-Objective Capital Asset Pricing Models by Multiple-Objective Portfolio Selection: Originating Multiple Risk-Free Assets and Proving the Tangency to Expected Utility Indifference Surfaces

Yue Qi, Nankai University, Tianjin, China, People's Republic of, ZhuJun Qi, Yue Wang

Markowitz originates portfolio selection as two-objective optimization. Sharpe considers one risk-free asset for portfolio selection and originates his capital asset pricing model as one center-piece of finance. Researchers contemplate capital allocation as constructing portfolios by one risky asset and one risk-free asset. Researchers maximize expected utility by locating the tangent point between a capital allocation line and an expected utility indifference curve. After their feat, Markowitz and Sharpe notice extra objectives. Researchers are advancing multiple-objective portfolio selection. However, there are still limitations in leaping from multiple-objective portfolio selection to multiple-objective capital asset pricing models. In such an area, this paper theoretically contributes to the literature. We originate multiple risk-free assets, extend traditional capital allocation, and prove the extension's plane property. We maximize expected utility by locating the tangency between a capital allocation plane and an expected utility indifference surface. Moreover, we prove that the tangency actually happens on a line instead of the traditional point. Overall, this paper theoretically acts as a foothold for eventually achieving multiple-objective capital asset pricing models.

3 - Pareto Set Domination Under Limited Information

Pubudu Jayasekara, The University of Tennessee at Chattanooga, Chattanooga, TN, United States, Margaret Wiecek

Mixed-integer multiobjective optimization problems typically yield nonconvex and disconnected sets of nondominated solutions, making the identification and analysis of the complete Pareto set particularly challenging. Their structural complexity demands the development of novel optimization approaches. While recent research has

increasingly focused on solving mixed-integer multiobjective problems, the concept of Pareto set domination, especially under limited information, has received relatively little attention.

This study addresses that gap by proposing a method to assess domination relationships among Pareto sets when complete information is unavailable. The proposed approach offers a structured way to compare partial or incomplete solution sets, which is particularly useful in iterative or heuristic-based optimization methods. Even with exact algorithms, generating the full Pareto set can be computationally expensive, making this approach broadly applicable. By evaluating dominance using only known nondominated points or subsets, the method enhances decision-making, and guides search strategies in complex problem settings.

Numerical examples are included to highlight its practicality and potential for wider use.

4 - Collision Avoidance and Path Finding in a Robotic Mobile Fulfillment System Using Multi-Objective Meta-Heuristics

Ahmad Kokhahi, Clemson university, Central, SC, United States, Mary Beth Kurz

This paper addresses the challenges of collision avoidance and task assignment in Robotic Mobile Fulfillment Systems (RMFS), where Automated Guided Vehicles (AGVs) coordinate to execute warehouse operations. While prior research primarily focuses on minimizing collisions and travel time, this study uniquely incorporates energy consumption into the optimization objectives. The proposed framework introduces a new rule to handle collisions by focusing on saving energy, based on whether AGVs are carrying a load or not. It also improves path planning using a modified A* algorithm that looks at both location and time, and changes routes in real time to avoid collisions, helping reduce delays and energy use.

For task assignment, two heuristic multi-objective approaches are developed: Non-Dominated Sorting Genetic Algorithm II (NSGA-II) and Adaptive Large Neighborhood Search (ALNS). Both techniques leverage custom neighborhood operators—swap, insertion, and arrangement—to cluster tasks by aisle proximity, minimizing travel distance and the likelihood of collisions. The NSGA-II algorithm incorporates a new Arithmetic Crossover (ARC) operator to better balance task distribution among AGVs.

Comprehensive computational experiments demonstrate the superior performance of the proposed methods in terms of both hypervolume and CSS metrics when compared to benchmark strategies. Notably, the improved NSGA-II algorithm consistently outperforms other variants. The findings suggest that energy-aware collision resolution and task assignment strategies can significantly enhance RMFS efficiency, offering valuable insights for warehouse operations management.

5 - Multi-Period Bioenergy Supply Chain Planning Incorporating Biomass Pricing

Leyla Tavassoli, Southern Methodist University, Dallas, TX, United States, Halit Uster

This study develops a planning framework for bioenergy supply chain networks that integrates both tactical and strategic decision-making by addressing spatial and temporal characteristics of the network design. We formulate a mixed-integer programming framework to capture the decisions on facility types and locations, their capacities, and multi-period shipment planning while taking into account farmers' biomass planting decisions. We implement decomposition-based algorithms and introduce enhancements to improve computational performance of our solution approach. The models are validated through computational experiments and a real-world case study in the Midwest United States using GIS-based spatial data.

6 - Optimizing Invasive Species Management with Bi-Objective Modeling and Gis Integration

Damitha Bandara, University of Tennessee-Chattanooga, Chattanooga, TN, United States, Lakmali Weerasena, Nyssa Hunt, Mark McKnight

Invasive species are costly and challenging to manage, highlighting the need for efficient control strategies. This study introduces a bi-objective optimization model integrated with GIS to support invasive species management (ISM). The model accounts for functional connectivity among infested sites and identifies optimal control strategies under varying minimum control levels. Applied to Chinese privet management across 317 acres in Chattanooga, Tennessee, the approach demonstrates how decision-makers' preferences and control targets influence outcomes. The results underscore the value of mathematical modeling in guiding ISM decisions and show how geographic visualization enhances practical strategy development.

7 - Optimizing Resource Allocation for Distribution System Upgrades for Resiliency Under Budget Constraints

Dhiraj Pokhrel, University of Tennessee, Knoxville, Knoxville, TN, United States, Hugh Medal

Severe blackout events due to extreme weather have been increasing in recent years, highlighting the need for resilient power distribution networks. In this research, we study the capacity expansion problem for upgrading the distribution grid under a budget constraint, with a focus on enhancing system resilience. We formulate our problem as a two-stage stochastic mixed-integer programming model to identify optimal investment decisions involving the placement and sizing of distributed generation units both renewable and non-renewable, as well as the placement of switches and line hardening measures. First stage decisions consist of infrastructure upgrades, while the second stage consists of operational responses post-disruption, aiming to minimize expected costs associated with generation, maintenance, and load shedding across all scenarios. We validate our model using the IEEE 33-bus test system, demonstrating the computational efficiency of our approach and the effectiveness of the proposed strategy in improving distribution grid resilience.

Advancements in Airline Revenue Management and Pricing

Invited Session

Air Transportation Section

Chair: Yuxuan Lu, 01801

1 - Capturing Choice Behavior in Revenue Management Systems Through a Passenger Schedule Preference Model

Caroline Muhith, Georgia Institute of Technology, Atlanta, GA, United States, Laurie Garrow

Passenger schedule preference models inform passenger behavior and decision-making, recognizing that passengers value itinerary attributes in addition to price. Business passengers, for example, often prefer specific departure and arrival times or nonstop flights, reflecting a lower tolerance for schedule deviations. These preferences contribute to the perceived disutility of a flight and indirectly impact demand. Currently, many revenue management (RM) systems lack customer schedule preferences. This paper introduces a schedule preference model into the customer decision making process that integrates three utility components: (1) a nonlinear replanning disutility, which penalizes deviations from ideal departure and arrival windows using a sigmoid function with modifiable beta, slope, and offset parameters to reflect behavioral sensitivities across passenger segments; (2) unfavored airline disutility, derived from the total airline seat share at the originating airport, to capture frequent flyer effects; and (3) a path-quality index disutility that penalizes itineraries with connections. This model was implemented in PassengerSim, a new competitive simulation tool for RM applications developed by Alan Walker, Jeff Newman, and Laurie Garrow on a network comprising four airlines, 44 cities, and 10 different fare classes. Preliminary results show that the airline with the most favorable schedule characteristics—more departures during peak time and higher seat shares at the originating airport—saw revenue increases of 1.3% to 2.0%, and system load factor improvements of 0.9% to 1.4%. These findings show how incorporating a schedule preference model into RM systems can accurately forecast and capture how itinerary features and demand impact revenue.

2 - Estimation of Price Sensitivity Using Passengersim Choice Set Data

Antonio Ramirez, Georgia Institute of Technology, Atlanta, GA, United States

Airline pricing and revenue management analysts continue to seek to understand how passengers choose what to book when presented with a set of travel itinerary options that vary in characteristics such as airline, price, and fare class. Without recreating a complete and comprehensive theoretical model, this research aims to determine the

feasibility of using basic multinomial logistic regression (MNL) models, which implicitly capture only limited aspects of customer choice, to estimate passenger price sensitivity. The choice set data used in our MNL models come from PassengerSim, a proprietary airline revenue management simulation tool, and are a random sample of nearly 10,000 choice sets from a simulation of a network comprising of four airlines, 44 cities, and 10 fare classes. We interpret the price-related coefficients from the fitted MNL models and roughly-converted FRAT5 values – the ratio between fares at which 50% of passengers sell-up – to examine price sensitivities separately by passenger type and booking window. Our results suggest that MNL models that account for airline, nonstop flights, and fare ratio (defined as price of alternative scaled by lowest available price in the choice set) and that rely on purchases-only choice set data (i.e., excluding no-go passengers) may produce reasonable price sensitivity estimates. Although, models that include no-purchase alternatives appear to be more robust at producing valid price sensitivity estimates. These findings suggest that an airline could use its own historical choice set and booking decision data to estimate price sensitivities and better gauge customer willingness-to-pay.

3 - Improving Airline Demand Forecasting Using Macroeconomic Trends and Sentiment Analysis

Soheil Sibdari, University of Massachusetts Dartmouth, North Dartmouth, MA, United States

Enhancing precision in demand forecasting is essential for airline profitability and operational efficiency. This research integrates historical sales data with macroeconomic indicators—such as GDP growth, exchange rates, energy prices, and middle-class expansion—and consumer sentiment analysis to improve airline demand forecasts. By combining economic forecasts with sentiment signals from news and public data, the model captures both financial trends and shifts in traveler behavior. A mathematical framework and empirical validation show that this approach improves predictive accuracy and supports dynamic decision-making in pricing, route planning, and capacity allocation. Using time series and spatial analysis, the study also captures regional and temporal variation, offering airlines more responsive and location-specific demand forecasts.

4 - Revenue and Load Factor Trade-off in Revenue Management

Darius Walczak, PROS Inc., Houston, TX, United States

The primary objective of revenue management (RM) is to maximize expected revenue and sophisticated software systems have been deployed to achieve it. In practice though, users of RM systems need to know what expected bookings and thus load factors are achievable under those controls. These key business metrics rival revenue in importance but have historically received less attention from the modeling perspective in RM.

We focus on the single-leg dynamic setting for which there are results available to generate the so-called efficient frontier between revenue and expected bookings/load factor. The efficient frontier makes the tradeoff between the two key RM metrics precise and interpretable.

Then, we extend our analysis to RM models with price-sensitive demand by broadening the concept of the fare class efficiency ('concave envelope') and the associated transformed fares/fare adjustments to account for the load factor objective. We also suggest ways to map network level load factor objectives to the corresponding individual flight-leg level objectives.

5 - Managing Congestion in Advanced Air Mobility Operations Using a Neural Network Enhanced Bi-Level Optimization Approach

Haochen Wu, University of Michigan, Ann Arbor, Ann Arbor, MI, United States

Advanced Air Mobility (AAM) represents an evolution of the air transportation system by introducing low-altitude, potentially high-traffic environments. AAM operations will be enabled by both new aircraft, as well as new safety- and efficiency-critical supporting infrastructure. Published concepts of operations from both public and private sector entities establish notions such as federated management of the airspace and public-private partnerships for AAM air traffic, but there is a gap in the literature in terms of integrated tools that consider all three critical elements: AAM fleet operators (lower layer), airspace service providers (middle layer), and overall system governance from the legacy air navigation service provider (upper layer). In this work, we explore modeling congestion management within the AAM setting using a bi-level optimization approach, focusing on (1) time-varying, stochastic AAM demand, (2) differing congestion management strategies, and (3) the impact of unscheduled, "pop-up" demand. We show that our bi-level formulation can be tractably solved using a Neural Network-based surrogate which returns solution qualities within 0.1–5.2% of the optimal solution. Additionally, we show that our congestion management strategies can reduce congestion by 25.7–39.8% when compared to the scenario of no strategies being applied. Finally, we also show that while pop-up demand degrades congestion conditions, our congestion management strategies fare better against pop-up demand than the no strategy scenario. The work herein contributes a rigorous modeling and simulation tool to help evaluate future AAM traffic management concepts and strategies.

Practical Applications

Invited Session

The Practice Section of Inform

Chair: Srinivas Bollapragada, GE Vernova Advanced Research Center, Niskayuna, NY, United States

1 - Real-Time Aircraft Engine-Informed Contrail Prediction and Joint Route and Airspace Optimization to Mitigate Co2 and Non-Co2 Aviation Emissions

Banu Gemici-Ozkan, Ph.D., GE Aerospace, Niskayuna, NY, United States, Saikat Ray Majumder, Guang Zhao, Anindya Bhaduri, Brett Matthews, Christopher Jerrett, Zhihui Yang, Jerrold Cline, George Dalakos

The aviation industry contributes to global warming through both CO2 emissions and non-CO2 effects. While the warming impact of CO2 emissions is well-established, accounting for approximately 2.5% of global anthropogenic contributions, non-CO2 effects—such as persistent contrails and NOx emissions—exert nearly double the radiative forcing compared to CO2 alone (Lee et al., 2021). In recent years, governments, private entities, and international organizations have intensified research efforts to quantify and validate the warming effects of contrails.

This presentation will summarize research conducted by GE Aerospace Research's Climate Sciences & Optimization Lab to minimize the overall warming effects of CO2 and non-CO2 emissions. The presentation will focus on two core areas:

Novel hybrid AI/ML and computer vision-based validation methods developed under the DOE ARPA-E-funded program, which introduces the Engine-Informed Prediction of Aviation-Induced Cirrus Trails (EPICTrails) system. EPICTrails integrates a real-time, in-flight prediction model to detect persistent contrails, validated at scale using satellite-based computer vision methodologies (achieving an F1-score ≥ 0.8 for contrails lasting 3+ hours).

A weather-informed flight and airspace optimization framework that jointly optimizes individual flight routes and multi-flight airspace utilization to minimize the combined warming effects of CO2 and non-CO2 emissions. Summary results using historical flight data will be presented to demonstrate the scaled impact of navigational avoidance strategies.

Together, these two research efforts represent a significant step toward reducing aviation's overall climate impact through advanced predictive modeling and operational optimization.

2 - Aircraft Engine Maintenance, Repair, and Overhaul Operations Optimization at GE Aerospace

Sohum Chatterjee, GE Aerospace, Niskayuna, NY, United States, Israel Beniaminy, David Toledano, Onur Dulgeroglu, Banu Gemici-Ozkan

Aircraft engine repair is a complex, multi-site operations management challenge that demands precise coordination across various stages and locations. After induction into the overhaul shops, each engine undergoes a detailed inspection and workscoping process to identify the necessary repairs or replacements. The core challenge lies in ensuring that all repair operations are completed efficiently and within target deadlines, enabling the timely return of engines to airline. This process requires periodic decision-making across multiple organizational levels, ranging from tactical day-to-day operations to strategic long-term planning, while balancing competing objectives. A complicating factor is the inherent uncertainty in the network, such as repair and supplier lead time variation or process yields that may require rework of certain parts.

In this work, we present GE Aerospace's approach to tackling these challenges, with a specific focus on optimizing the process of part allocation to replace scrapped components in overhaul engines. Part allocation is a critical process that ensures the optimal use of the spare part pool by allocating the right quantities to the right engines at the right time. We develop a multi-objective mixed-integer programming model and generate solutions that significantly improve fleet repair performance over current allocation practices. Preliminary results illustrate improved decision-making efficiency, reduced launch delays, and significantly enhanced throughput rates.

3 - Cogeneration Power Plant Dispatch Problem

Rajesh Tyagi, Retired, Plainsboro, NJ, United States

In a cogeneration power plant, an assembly of gas turbines, steam turbines and other auxiliary units such as boilers and duct burners work in tandem to produce electric power and steam. The operational settings that minimize fuel cost for meeting energy demand requirements, possibly over multiple cogeneration blocks, entails diligent adjustments across settings and blocks, whose combinatorics favor a complex optimization solution. We describe the problem and suggest a practical solution approach.

4 - Optimal Scheduling of Field Resources for Power Plant Outages

Rajeev Namboothiri, GE Vernova Research, Bangalore, India

GE Vernova's Gas Power Business installs and supports power generation equipment around the world. These power plants undergo periodic planned outages and forced unplanned outages to ensure safe and efficient operations. These outages require mobile field resources with specific skillset for a specific duration to perform maintenance tasks. A host of additional constraints restrict the eligibility and availability of a field resource to perform a maintenance task. The Business centrally manages the deployment of field resources to power plant outages through five different regions. We developed a Field Resource Optimizer product to provide resource scheduling recommendations to minimize the total cost associated with field service operations while meeting all the real-world constraints associated with assigning field resources to outage tasks. The standard optimization formulation of the field resource allocation problem results in a mixed integer linear program that is too large to be solved in a reasonable amount of time for practical use. We therefore developed a novel solution procedure that iteratively solves a series of linear programs to achieve the optimal solution within a few minutes. The Business is actively using this tool since 2024, resulting in significant operational cost savings.

5 - Wind Turbines Services Optimization

Srinivas Bollapragada, GE Vernova Advanced Research Center, Niskayuna, NY, United States

This work focuses on developing advanced optimization algorithms and software tools to enhance the servicing of onshore wind turbines. The primary goals are to improve customer satisfaction, reduce service costs, and strategically position the services organization for the anticipated significant growth in the installed base of onshore wind turbines. To achieve these objectives, we have designed and implemented a suite of optimization solutions and digital tools that are currently deployed at GE Vernova, delivering measurable improvements in service operations.

6 - Is Data-Driven Failure Early Warning Possible for Wind Turbines?

Yu Ding, Georgia Institute of Technology, Atlanta, GA, United States

Unexpected failures in engineering systems lead to expensive maintenance actions and should be avoided if at all possible. This is particularly true for wind turbine systems, for which unexpected failures not only demand costly repairs but also cause long downtime. Currently early warning systems work based on physically verified symptoms, much like in human illness early warning. A domain expert identified a symptom (like a crack), which, once initiated, will eventually lead to failure. When the enabling domain knowledge is available, an early warning problem can be converted to a regular change or anomaly detection problem. The limitation is that practitioners do not always know which symptoms to look for. It is also rather costly to thoroughly screen the whole turbine system on a frequent basis for the onset of certain damage inception conditions. On the other hand, modern wind turbines (in fact for most modern engineering systems) are equipped with a range of sensors, forming a system known as SCADA (supervisory control and data acquisition) that collects data continuously. The speaker wants to shed some lights on the question whether one can provide early-warning capability by just using the SCADA data.

Health and Holistic Fitness: Using Big Data from Wearables, Free Text, and Clinical Sources to Make Personalized Decisions

Invited Session

Military and Security

Chair: Russell Nelson, United States Military Academy, West Point, NY, United States

Co-Chair: Diana Thomas, United States Military Academy, West Point, NY, United States

1 - Mining Pubmed with LLMs: Enhancing Literature Synthesis with AI

Jonathan Day, United States Military Academy, West Point, NY, United States

We conducted a large-scale natural language processing (NLP) analysis of 7,366 medical research articles related to precancerous breast lesions, including lobular proliferative hyperplasia (LPH), atypical ductal hyperplasia (ADH), lobular carcinoma in situ (LCIS), flat epithelial atypia (FEA), and other atypical proliferative lesions. Articles were retrieved using a hybrid web scraping framework combining BioEntrez and Selenium. To explore latent themes and synthesize findings across the literature, we generated document embeddings using both BERT-based contextual models and TF-IDF representations. These embeddings were then analyzed through unsupervised learning methods, including clustering algorithms (e.g., K-Means, DBSCAN) and pairwise similarity metrics (cosine similarity and alternative distance measures), to produce interpretable visualizations of thematic groupings. Additionally, we employed abstractive summarization models such as BART and PEGASUS to distill clinical insights, with a specific focus on statistical measures commonly reported in epidemiological studies—odds ratios (OR), hazard ratios (HR), and relative risks (RR). Our analysis offers a novel approach in achieving objective, reproducible synthesis of complex and heterogeneous literature. Our machine learning-driven framework demonstrates the potential for automating literature triage, identifying emergent subtopics, and enhancing interpretability through scalable, data-driven summarization. These findings suggest that NLP tools can augment the systematic review process, enabling a more nuanced and statistically enriched understanding of the evolving field of precancerous breast pathology.

2 - From Device to Model: Extracting Insight From Cgm Metrics

Austin Semmel, North Carolina State University, Raleigh, NC, United States

Despite their name, continuous glucose monitors (CGMs) face the reality of discretized monitoring intervals, which presents an inherent tradeoff between measurement frequency and device longevity due to battery constraints. This limitation creates challenges for extracting insights from CGM data. Missing data points and varied reading intervals both significantly impact the consistency of derived glycemic metrics, making it difficult to compare results across studies and inform personalized readiness strategies. We developed a Python-based application that addresses these issues by accepting raw CGM data from any device, performing automated preprocessing, and calculating over 15 validated metrics. The tool emphasizes transparency and reproducibility with standardized metric definitions and user-adjustable parameters for handling missing data. We demonstrate the importance of considering data completeness thresholds and reading intervals (5, 10, 15 minutes, etc.) when assessing metric consistency, as these factors substantially influence metric values and their subsequent interpretation. The tool's output files integrate with statistical modeling and machine learning applications to drive inferences from CGM data. CGM data does not lend itself to "one-size-fits-all" analysis. Harnessing this mindset, we provide a standardized, multi-metric approach to CGM data analysis. Our tool supports clinical decision-making and large-scale research initiatives aimed at understanding patterns of both glycemic control and variability. This work represents a critical step towards harnessing the potential of CGM technology to inform personalized strategies for optimizing individual glycemic control and overall health, ultimately contributing to improved readiness across the force.

3 - The Chemistry of Health: How Metabolomics is Redefining Precision Medicine

Blake Rushing, Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC, United States

Metabolomics, the comprehensive study of small molecules or metabolites in biological systems, offers a unique and powerful lens through which to study human health. As the “ome” closest to phenotype, the metabolome serves as a dynamic readout of gene activity, environment, diet, and lifestyle. These interactions shape metabolic pathways that regulate a wide array of biological outcomes such as energy production, immune response, detoxification of xenobiotics, gene expression, and much more. As such, metabolomics is increasingly recognized as an essential tool in biomedical research and precision health. This talk will introduce core concepts of metabolomics, including how high-resolution analytical techniques—primarily mass spectrometry—are used to capture thousands of features from biological samples like blood, urine, cells, and tissues. These data can be analyzed to uncover disrupted pathways, detect early signs of disease, design nutritional/pharmacological interventions, or evaluate responses to interventions such as diet, medication, or environmental exposures. Finally, we will consider the future of metabolomics in advancing precision nutrition and medicine. By integrating metabolic profiles with genetic and environmental data, researchers can better understand disease risk and response at the individual or subpopulation level. The ultimate goal is to translate this information into actionable strategies that promote health and prevent disease.

4 - Fusing Multi-Modal Health Data for Personalized Predictions: Toward Integrated Health Modeling

Jake LaPorte, United States Military Academy, West Point, NY, United States

As the number of digital health monitors increases and the cost of these devices decreases, it is possible for individuals to continuously monitor their health, activity level, and how their body interacts with food. A significant challenge comes with the sheer volume of physiological data associated with these devices in the form of turning this raw data into meaningful, actionable information for the user, along with practical insights into each person's health. The focus of this talk is the modeling technique used to transform accelerometer data into steps per day and peak-30 cadence using publicly available data, feature engineering, and a predictive, ensemble model that includes a classification model which feeds a regression model.

High-Dimensional Stochastic Controls Problems in Operations Management

Invited Session

Applied Probability Society

Chair: Yuan Zhong, University of Chicago, Chicago, IL, United States

1 - Polynomial TIME Approximation Schemes for Online Resource Allocation with General Correlations

David Goldberg, Cornell University, Ithaca, NY, United States, Yilun Chen, Umur Cetin

There has been a growing interest in studying online resource allocation problems such as network revenue management under more general correlation structures, motivated by the complex data sets, generative models, and high-variance phenomena driving modern applications. Several interesting recent works either posit a particular structure for the possible correlations, have a complexity scaling with the number of Markovian “states of the world” (which may be exponentially large), or make additional continuity assumptions.

We show that the NRM problem (suitably normalized) has an additive Polynomial Time Approximation Scheme (with runtime independent of the number of “states of the world”) under a completely general model of correlations, assuming access to a natural Monte Carlo simulator for the demand dynamics, and that the maximum number of resources used by a product is uniformly bounded.

In contrast to several past works on PTAS for multi-stage stochastic linear programming with runtime exponential in the time horizon, our methods have a runtime essentially independent of the horizon altogether.

At the heart of our algorithms is a new way to conceptualize and implement stochastic gradient methods on-the-fly/recursively for the massive linear programs (on scenario trees, i.e. deterministic-equivalent problem) associated with natural relaxations of these problems, based on the simple idea that to implement a policy one needs only compute the relevant values along the sample path presented to you.

We also derive new algorithms and insights for several online combinatorial optimization problems with general correlation structure on bounded degree (random) graphs.

2 - Dynamic Scheduling of a Multiclass Queue in the Halfin-Whitt Regime: a Computational Approach for High-Dimensional Problems

Ebru Kasikaralar, University of Chicago, Booth School of Business, Chicago, IL, United States, Baris Ata

We consider a multi-class queueing model of a telephone call center, in which a system manager dynamically allocates available servers to customer calls. Calls can terminate through either service completion or customer abandonment, and the manager strives to minimize the expected total of holding costs plus abandonment costs over a finite horizon. Focusing on the Halfin-Whitt heavy traffic regime, we derive an approximating diffusion control problem, and building on earlier work by Beck et al. (2021), develop a simulation-based computational method for solution of such problems, one that relies heavily on deep neural network technology. Using this computational method, we propose a policy for the original (pre-limit) call center scheduling problem. Finally, the performance of this policy is assessed using test problems based on publicly available call center data. For the test problems considered so far, our policy does as well as or better than the best benchmark we could find. Moreover, our method is computationally feasible at least up to dimension 500, that is, for call centers with 500 or more distinct customer classes.

3 - A Computational Method for Solving the Stochastic Joint Replenishment Problem in High Dimensions

Wouter van Eekelen, The University of Chicago Booth School of Business, Chicago, IL, United States, Baris Ata, Yuan Zhong

We consider a class of stochastic joint replenishment problems in a high-dimensional setting. First, we approximate the problem by a multi-dimensional impulse control problem. Exploiting connections among the impulse control problem, backward stochastic differential equations (BSDEs) with jumps, and the stochastic target problem, we develop a simulation-based computational method that relies on deep neural network technology. We test our proposed policy against the best available benchmarks in the context of the original stochastic joint replenishment problem. For the test problems studied thus far, our method is as good or better than the best benchmark we could find, and it is computationally feasible up to at least 100 dimensions—that is, 100 stock-keeping units (SKUs).

4 - Multi-Agent Markov Entanglement

Shuze Chen, Columbia University, New York City, NY, United States, Tianyi Peng

Value decomposition has long been a fundamental technique in multi-agent reinforcement learning and dynamic programming. Specifically, the value function of a global state $(s_1, s_2, \dots, s_N)$ is often approximated as the sum of local functions: $V(s_1, s_2, \dots, s_N) \approx \sum_i V_i(s_i)$. This approach has found various applications in modern RL systems. However, the theoretical justification for why this decomposition works so effectively remains underexplored. In this paper, we uncover the underlying mathematical structure that enables value decomposition. We demonstrate that a Markov decision process (MDP) permits value decomposition *if and only if* its transition matrix is not “entangled”—a concept analogous to quantum entanglement in quantum physics. Drawing inspiration from how physicists measure quantum entanglement, we introduce how to measure the “Markov entanglement” and show that this measure can be used to bound the decomposition error in general multi-agent MDPs. Using the concept of Markov entanglement, we proved that a widely-used class of policies, the index policy, is weakly-entangled and enjoys a sublinear $O(\sqrt{N})$ scale of decomposition error for N -agent systems. Finally, we show Markov entanglement can be efficiently estimated, guiding practitioners on the feasibility of value decomposition.

5 - Multilevel Picard Approximations for Drift Rate Controls with State Constraints

Yuan Zhong, University of Chicago, Chicago, IL, United States

Motivated by applications to queueing network controls, we develop a multi-level Picard (MLP) approximation scheme for solving high-dimensional drift rate control problems whose states are constrained to stay within the nonnegative orthant. We prove that under suitable conditions, the MLP scheme provably overcomes the curse of

dimensionality. In our numerical experiments, the scheme is shown to be computationally feasible for problems up to dimension 20.

1 - Assessing the Capacity of Railway Network Control Points with Monte Carlo Simulation

Jiayi Zhao, DB E.C.O. North America, San Gabriel, CA, United States, Darkhan Mussanov, Yasmin Ara

Evaluating the capacity of control points, especially in dense railway traffic regions such as St. Louis, is critical for strategic planning and congestion management. However, existing modeling tools often require detailed knowledge of both the physical layout of infrastructure elements (e.g., diamonds, leads from yards to mainlines, and junctions) and train schedules. This study introduces a simulation-based parametric methodology to estimate the capacity of these key control points without relying on detailed layout measurements or operational timetables. The approach begins by generalizing control point configurations into abstract movement patterns that capture common train interactions such as crossings, merges, and divergences. Monte Carlo simulation is then used to model train movements through these control points over defined time intervals, capturing stochastic occupancy patterns and conflict dynamics. Capacity is quantified in terms of the number of feasible train movements per time period under varying traffic conditions. Moreover, multiple control points can be aggregated to represent larger, more complex network regions, enabling evaluation of cumulative capacity. This flexible, data-light approach supports scalable assessments across diverse network topologies and operational uncertainties. The results provide critical insights into throughput limitations in high-density corridors and can inform decisions on bottleneck mitigation, infrastructure investment, and strategic rail planning. By abstracting physical and temporal specifics, the method enables early-stage capacity analysis and comparative evaluations across urban rail systems. This work contributes a practical tool for rail network operators, planners, and researchers seeking efficient, layout-independent methods for capacity evaluation.

2 - An Outer-Inner Approximation Method for the Generic Choice-Based Optimization Problem

Haoye Chen, KTH Royal Institute of Technology, Stockholm, Sweden, Jan Kronqvist, Ma Zhenliang

Choice-based optimization problem integrates demand modeling into optimal supply decisions, which is generic for decision-making applications. Solving the problem is challenging given the nonlinear discrete choice model constraints. Existing solution methods are limited to specific problem structures, such as binary or discrete supply decisions and fixed option attributes. This paper proposes an outer-inner approximation method for the generic choice-based optimization problem without specific problem structural requirements. We validated the method using a network expansion problem on the Sioux Falls network, aiming to reduce the overall system congestion by optimally expanding road capacities considering the road expansion cost. The results show that the expansion cost is significantly lower than the total travel time savings. More experiments are expected to benchmark with existing models using more case studies, e.g., service frequency and pricing in multimodal transportation systems.

3 - OneBOM: Accelerating Railcar Quoting and Improving Supply Chain Accuracy with AI and Analytics

Garrett Mucha, Trinity Industries, Dallas, TX, United States

Trinity Industries has developed OneBOM, an AI-powered platform that transforms how the company estimates costs, builds quotes, and aligns supply planning for complex, custom-engineered freight railcars. Built in Palantir Foundry, OneBOM consolidates five engineering BOM sources into a unified data model that supports rapid, accurate quoting and provides a consistent foundation for supply chain planning.

A key innovation is the integration of generative AI to bridge engineering specifications and BOM creation. Trinity's "Spec-to-Spec diff" capability compares incoming customer specs against historical builds, highlighting key design changes and mapping them directly to affected BOM elements. This allows estimators to bypass manual BOM construction and instead generate quote-ready BOMs directly from specification changes—reducing cycle time and improving consistency.

OneBOM also features advanced cost modeling that calculates material, labor, and overhead in real time, allowing estimators to understand cost impacts instantly. Alternate parts logic and reusable templates further speed up the quoting process while preserving flexibility and accuracy.

On the supply side, BOM harmonization improves forecast precision. Cleaned and structured BOMs now feed reliable demand signals into procurement models, improving long-lead material planning and reducing inventory risk.

With OneBOM, Trinity has cut quoting effort by 80%, improved supply chain forecast accuracy, and enabled a more agile response to customer-specific requirements. The platform showcases how GenAI and analytics can modernize railcar manufacturing by aligning engineering data, cost estimation, and procurement into a unified digital workflow.

4 - Comparative Analysis of Machine Learning and Traditional Methods in Predicting Railroad Operational Metrics

Muhammad Ramahi, TTX Company, Charlotte, NC, United States

We present an in-depth exploration of a novel technique for forecasting critical railroad operational metrics, specifically focusing on cycle-time and railcars network mileage. The primary objective is to compare and contrast the efficacy of emerging machine learning techniques with traditional classical methods in predicting these metrics for various fleets.

Cycle time, which refers to the total time taken for a railcar to complete a full cycle from departure to return, is a crucial component of the business planning process.

Accurate prediction of cycle-time is essential as it helps determine the number of railcars required to meet network demand efficiently. An accurate forecast ensures that there are neither too many idle railcars nor too few to meet the demand, thereby optimizing operational efficiency and cost-effectiveness.

On the other hand, predicting railcars network mileage, which is the total distance covered by railcars within the network, is vital for planning and budgeting equipment maintenance. Accurate mileage predictions enable better scheduling of maintenance activities, ensuring that railcars are serviced at appropriate intervals to prevent unexpected breakdowns and extend their operational lifespan. This not only enhances the reliability and safety of the rail-network but also helps in optimizing maintenance budgets.

By leveraging machine learning techniques, which can analyze vast amounts of data and identify complex patterns, we aim to improve the accuracy and reliability of these forecasts. This study will provide valuable insights into the potential advantages and limitations of machine learning compared to classical methods, ultimately contributing to more efficient and effective railroad operations.

5 - Dynamic Routing for Intermodal Container Transportation

Qianqian Tong, University of Texas at Austin, Austin, TX, United States, Tyler Dick

North America's rail-road intermodal container transportation system handles over 18 million units annually. With the rapid growth of container shipment demand across the country, efficient routing methods within and between intermodal terminals play a critical role in achieving both strategic and operational goals. This study assigns daily container flows across intermodal routes by minimizing weighted travel time, cost, and energy per container to support planning-level mode choice decisions for container transportation. To consider congestion and delay effects in routing and capacity planning, this study also proposes a two-layer simulation-based framework for container route choice. At the node level, we derive node performance functions (NPFs) using SimPy-based discrete-event simulation, where optimal layout and vehicle performance parameters are used to evaluate how terminal yard scale and resource combinations influence container processing efficiency. At the link level, we apply the Advanced Locomotive Technology and Rail Infrastructure Optimization System (ALTRIOS) to simulate and obtain link performance functions (LPFs) to capture the dynamic performance of mainlines, and also apply the Bureau of Public Roads (BPR) function to describe the performance of adjacent roadways under traffic. Integrating NPFs and LPFs within a dynamic traffic assignment framework, we merge them to create a dynamic container routing model to provide strategic guidance for intermodal

network design and operations planning. To demonstrate the applicability of our approach, we implement our model in a Texas-based case study to examine how strategic and tactical decisions to improve efficiency can be made regarding both vehicle technologies and infrastructure configurations.

3 - Conformal Inverse Optimization for Adherence Aware Prescriptive Analytics

Bo Lin, University of Toronto, Toronto, ON, Canada

Inverse optimization has been increasingly used to estimate unknown parameters in an optimization model based on decision data. We show that such a point estimation is insufficient in a prescriptive setting where the estimated parameters are used to prescribe new decisions. The prescribed decisions may be low-quality and misaligned with human intuition and thus are unlikely to be adopted. To tackle this challenge, we propose conformal inverse optimization, which seeks to learn an uncertainty set for the unknown parameters and then solve a robust optimization model to prescribe new decisions. Under mild assumptions, we show that the suggested decisions can achieve bounded out-of-sample optimality gaps, as evaluated using both the ground-truth parameters and the decision maker's perception of the unknown parameters. Our method demonstrates strong empirical performance compared to classic inverse optimization.

1 - Redundancy OR Flexibility? Interplay Between Their Values in Designing Fork-Join Systems

Chutong Gao, Northwestern University, Evanston, IL, United States, Seyed Iravani, Ohad Perry

We consider fork-join systems with redundancy and flexibility. Fork-join systems are widely employed in online service platforms, among other real-world applications. In a k -requirement fork-join (FJ_k , $k \geq 2$) system, a job "forks" (i.e., divides) into k tasks which are processed in parallel stations; after completion, these k tasks then "join" together to finish the job. To minimize job sojourn times in FJ_k systems, two strategies---redundancy and flexibility---are often employed. Redundancy deploys $n \geq k$ stations and sends one task to each server, but only k out of n tasks are needed to complete each job. Flexibility enables dynamic service capacity allocation across stations at any time. To understand the value of each strategy and their interplay in reducing sojourn times, we propose a unified modeling framework that simultaneously considers: (i) how many redundant stations should be established, and (ii) how the service capacity should be allocated among all stations. With flexibility, we characterize the optimal dynamic capacity-allocation policy, under which redundancy does not offer any additional value in FJ_k systems. In contrast, in the absence of flexibility, for $k=2$, we prove "a little redundancy goes a long way" in a twofold sense: To achieve asymptotic optimality relative to the best system with flexibility, it suffices to (i) employ only one extra station, making $n=k+1$, and (ii) allocate an arbitrarily small capacity $\epsilon > 0$ to that extra station. This suggests that (even a little) redundancy is as attractive as (full) flexibility. Extensive numerical studies further extend the insights to general FJ_k systems.

2 - A near-Optimal Control Policy for Data-Driven Assemble-to-Order Systems

Zhixuan Cai, Tsinghua University, Beijing, China, People's Republic of, Lun Yu, Zhaoran Wang, Tianhu Deng

We study a data-driven control of assemble-to-order (ATO) systems, aiming to synchronize between components' ordering decisions under non-identical lead times and products' assembly under unknown demand distribution. To the best of our knowledge, our work is the first to analyze the sampling effectiveness of general ATO system as high-dimensional control problem on noncompact domain and the first to propose an algorithm that finds a near-optimal solution. Surprisingly, we prove that the data-driven ATO control problem does not suffer from the curse of dimensionality, in the sense that the performance gap between the best data-driven control policy and the intractable optimal policy is only logarithmically larger than the gap between sample mean and expectation. With a novel utilization of an important convex property of ATO transition dynamics, we develop a specialized reinforcement learning (RL) algorithm that is applicable to the control problem, which also provably achieves the best performance gap. An extensive numerical study supports that a close-to-optimal policy of the general ATO system is obtainable using small demand samples, where the proposed algorithm consistently and notably outperforms existing heuristic policies and an off-the-shelf RL algorithm.

3 - Functional Limits of Generalized Jackson Networks in Multi-Scale Heavy Traffic

Jin Guang, The Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Zhen-Qing Chen, Jim Dai

We investigate the process-level convergence of generalized Jackson networks (GJNs) in multi-scale heavy traffic recently proposed by Dai, Glynn, and Xu (2023), which yields a limit with a product-form stationary distribution. Although this regime effectively approximates the stationary distribution, it does not provide insights into the temporal evolution of the process or explain why each component becomes independent. In this paper, we demonstrate that a sequence of GJNs converges weakly to a limiting process with independent components, offering a deeper understanding of their temporal dynamics and independence structure. Additionally, we extend the multi-scale heavy traffic regime to a block-scale heavy traffic regime, where the components are divided into blocks, and each block is scaled at the same rate. We prove that process-level convergence holds in this regime as well, and the limiting process exhibits block-wise independence. Our results provide a new perspective on the temporal behavior of GJNs in multi-scale and block-scale heavy traffic regimes.

4 - Electrifying the Fleet: Dimensioning Electric Vehicle Sharing Systems

Jingyuan Wan, University of Michigan, Ann Arbor, MI, United States, Saif Benjaafar, Martin Zubeldia

We consider a system of shared electric vehicles that operates on an on-demand basis over a spatial network of multiple locations. Customers arrive at each location and, if there is a vehicle available, they travel to another location where the vehicle is dropped off. At each location, there is a finite number of chargers that can be used by the vehicles. We model this system as a closed queueing network and derive closed-form lower and upper bounds on the minimal fleet size and number of chargers at each location so that the fraction of demand unfulfilled and average waiting time for charging are below predetermined target service levels. The upper bounds imply

dimensioning rules that guarantee the target service levels. We show that the dimensioning rules implied by these bounds are asymptotically optimal. More significantly, these dimensioning rules are highly interpretable with separable components that can be attributed to different drivers of capacity. We leverage the upper and lower bounds to propose an approximation of the optimal capacity that is always between the upper and lower bounds and is asymptotically optimal and otherwise exhibits strong performance as validated by extensive numerical experiments. We show how the results we obtain can be used to examine the tradeoff between fleet size and size of charging infrastructure and assess the impact of electrification.

5 - Cascading Bandits for Periodic Recommendations: Handling Delayed Feedback and User Retention

Dairui Wang, Tsinghua University, Beijing, China, People's Republic of, Junyu Cao, Wei Qi

Delayed feedback is a critical problem in dynamic recommender systems. In practice, the feedback result often depends on the frequency of recommendation. Most existing online learning literature fails to consider optimization of the recommendation frequency, and regards the reward from each successfully recommendation as equal. In this work, we consider a novel cascading bandits setting, where individual messages from a selected list are sent to a user periodically. Whenever a user does not like a message, she may abandon the system with a probability positively correlated with the recommendation frequency. A learning agent needs to learn both the underlying message attraction probabilities and users' abandonment probabilities through the randomly delayed feedback. We first show a dynamic programming solution to finding the optimal message sequence in deterministic scenarios, in which the reward is allowed to vary with different messages. Then we propose a polynomial time UCB-based offline learning algorithm, and discuss its performance by characterizing its regret bound. For the online setting, we propose a learning algorithm which allows adaptive content for a given user, and its regret bound is also discussed. Numerical experiment on NetEase Cloud Music dataset confirms the effectiveness of our algorithms, and clarifies the value of contextual information in recommender systems.

1 - Towards Inclusive and Human-Centered AI: Research and Service at the Intersection of Algorithms and Society

Juba Ziani, Georgia Tech, Atlanta, GA, United States

Research-wise, my work reframes fairness not as a purely technical constraint but as a property that emerges from the broader socio-economic processes in which AI and decision making is deployed. I will briefly discuss how my research draws on tools from computer science, operations research, and economics to study short-term and long-term disparities and the social impact of algorithmic decisions. Service-wise, I have been striving to build structures that support the development of young researchers and inclusivity in our research communities. I will highlight some of these efforts—including founding the ISyE Rising Stars Workshop, leading the EAAMO Doctoral Consortium for the past 4 years, and developing mentoring and outreach programs aimed at broadening participation not only in OR but also in computing.

2 - Bringing the Energy Transition to Underserved Texas Communities: the City of Dallas Green Warriors Weatherization Pilot

Erick Jones, University of Texas at Arlington, Arlington, TX, United States

Various federal, state, and local programs aim to improve energy outcomes for underserved low-income households. They mainly target the inefficient housing envelopes prevalent but new efforts have aimed to incorporate energy generation and storage as well. Nonetheless, administrative not technical hurdles provide the most resistance to successful deployment of these programs. Organizations design programs to address a specific challenge and often find other factors that are not budgeted for affect the efficacy of their targeted intervention. This either results in interventions that are less effective than originally planned or a shrinking pool of potential candidates. These challenges frustrate residents as the promised benefits never arrive even filling out an exhaustive level of paperwork and waiting years. To address this issue our team created a pilot program in South Dallas, a majority Black and low-income neighborhood, to weatherize homes using local contractors (Green Warriors) that overcomes previous barriers to success. To illustrate the efficacy of the program we collected data before and after the weatherization and are creating a replicable framework to be used for future projects.

Two New Applications of the Gittins Index: Tail Scheduling and Bayesian Optimization

TutORial session

TutORials

Chair: Nilay Noyan, AMAZON, Bellevue, WA, United States

1 - The Gittins Index: A Design Principle for Decision-Making Under Uncertainty

Ziv Scully, Cornell University, Ithaca, NY, United States, Alexander Terenin

The Gittins index is a tool that optimally solves a variety of decision-making problems involving uncertainty, including multi-armed bandit problems, minimizing mean latency in queues, and search problems like the Pandora's box model. However, despite the above examples and later extensions thereof, the space of problems that the Gittins index can solve perfectly optimally is limited, and its definition is rather subtle compared to those of other multi-armed bandit algorithms. As a result, the Gittins index is often regarded as being primarily a concept of theoretical importance, rather than a practical tool for solving decision-making problems.

The aim of this tutorial is to demonstrate that the Gittins index can be fruitfully applied to practical problems. We start by giving an example-driven introduction to the Gittins index, then walk through several examples of problems it solves—some optimally, some suboptimally but still with excellent performance. Two practical highlights in the latter category are applying the Gittins index to Bayesian optimization, and applying the Gittins index to minimizing tail latency in queues.

Coordinated Collaboration and Logistics Risk Management

Invited Session

TSL: Freight Transportation

Chair: Ilke Bakir, University of Groningen, Groningen, Netherlands

1 - A New Perspective on Carrier Collaboration: Collaborative Vehicle Utilization

Ilke Bakir, University of Groningen, Groningen, Netherlands, Sahand Asgharieh Ahari, Kees Jan Roodbergen

We study a centralized collaboration mechanism for logistics carriers based on the shared use of vehicle fleets, which we refer to as Collaborative Vehicle Utilization (CVU). While most collaboration frameworks focus on order sharing, where carriers deliver on each other's behalf, CVU enables carriers to lend and borrow vehicles

while retaining full control over their own delivery operations. This avoids the need to share sensitive customer or operational data, making collaboration more viable in practice. CVU also supports sustainability efforts by improving vehicle utilization and reducing the need for fleet expansion, which is particularly relevant given the environmental footprint of vehicle production and the limited scalability of electric truck manufacturing in the coming years. We explore CVU in three collaborative vehicle routing settings. For each setting, we develop formulations, branch(-cut)-and-price methods, and heuristics. In the single-period setting, we compare CVU to order sharing and non-collaborative operations and find that CVU achieves similar profits while offering substantial computational advantages. In a multi-period extension, where customers require consistent delivery time windows, CVU reduces network-level fleet size by up to 45% and increases profit by up to 15%. Finally, we apply CVU to a two-echelon urban logistics system, where large trucks operate from distribution centers to satellites and smaller vehicles deliver to customers, potentially through multiple trips starting and ending at the satellites. In this variant, carriers may share vehicles in both echelons and optionally share satellite capacity, which further improves vehicle utilization and yields additional profit gains.

2 - Improving Supply Chain Resilience with Information Sharing Through a Central Platform

BATUHAN Celik, Rensselaer Polytechnic Institute, Troy, NY, United States, Bahar Cavdar, Jennifer Pazour

The ability of supply chain players to adapt and change decisions in response to disruptions is key to increasing resiliency. However, disruptions are observed asynchronously, reducing the supply chain's collective response and amplifying disruption impacts. These effects can be alleviated through information sharing, but firms hesitate due to strategic risks. To address this, we design an information-sharing policy for competing firms to improve supply chain resilience. A key characteristic of the designed policies is to ensure that players maintain decision autonomy and competitive power. We explore how sharing disruption information affects profit-oriented equilibrium strategies and resilience, using a central platform. We aim to design a platform that determines optimal information-sharing policies to maximize resilience while players act according to profit-oriented objectives. We use a game-theoretic model of a two-echelon supply chain with distributors and retailers. We analyze when resilience aligns or conflicts with personal objectives and develop a mechanism to incentivize players to participate in the platform, namely committed sharing. We examine the impact of network structure, disruption type, player characteristics and participation on resilience and profit under this sharing approach. We identify which distributors' participation benefits resilience and set platform parameters for large-scale supply chains with an optimization model. We show how supply chain characteristics impact sharing behavior and resilience, offering insights for policymakers and academics designing platforms that consider system-wide objectives while improving decision-making under uncertainty.

3 - A Mean-Variance Optimization Model for Produce Export Distribution with Postponed Shipment and Market Allocation Option

Alejandro Mac Cawley, Pontificia Universidad Catolica de Chile, Santiago, Chile, Nicolás Vargas, Mathias Klapp

This research addresses the challenge of managing price risk in the allocation decisions of exporters of perishable agricultural products, such as grapes or apples, sold in geographically dispersed spot markets characterized by volatile and correlated prices and long transit times. We propose a methodology that extends the classic Markowitz Mean-Variance (MV) model, presenting a two-stage stochastic optimization framework that maximizes the operation's net income subject to a maximum acceptable income variability. Traditional risk management and optimization models often overlook diversification and recourse risk management strategies. The proposed model allows decision-makers to use three risk-mitigation strategies: distribute shipments across multiple markets (inter-market diversification), distribute shipments in multiple moments, and delay a fraction of their shipment allocation decisions to a later stage (inter-temporal diversification). Diversifying shipments across multiple markets and shipment moments allows the exporter to exploit negative price correlations, reducing volatility for a given expected income. Delaying shipment allocation decisions allows the decision-maker to rely on updated price information, reduce uncertainty, and increase expected net income for a given level of risk tolerance. The study demonstrates the value added by combining inter-market, multiple shipment moments, and inter-temporal diversification strategies, especially when product inventory costs are manageable.

Applications of Agent-Based Modeling and Simulation in Decision Analytics for Public Services

Invited Session

Simulation

Chair: Yuan Zhou, University of Texas at Arlington, Arlington, TX, United States

1 - Modeling Criminal Behavior in Urban Environments Using Criminological Theory and Agent-Based Simulation

Shohreh Moradi, The University of Texas at Arlington, Arlington, TX, United States, Yuan Zhou, Victoria Chen, Jay Rosenberger, Christi L Gullion, Chen Kan

Understanding the dynamics of urban crime requires theoretical frameworks that capture the interplay between individual behavior, routine activity, and environmental context. A theory-driven approach to modeling criminal behavior via an agent-based simulation is presented, grounded in three key criminological theories: Routine Activity Theory (RAT), Rational Choice Theory (RCT), and Crime Pattern Theory (CPT). These theories inform the decision-making rules and interactions among offenders, law enforcement officers, and citizens within the model. RAT provides the foundational structure for identifying potential crime events, emphasizing the convergence of motivated offenders, suitable targets, and the absence of capable guardians. RCT shapes offender behavior by modeling decisions based on perceived costs and benefits. CPT introduces spatial logic by anchoring agent routines and interactions within urban activity nodes and pathways. Together, these theories enable the generation of realistic, emergent crime patterns from micro-level agent decisions. By embedding these frameworks in the simulation architecture, the model serves both as a testbed for theoretical exploration and a foundation for practical applications in crime prevention. The results demonstrate the value of theory-informed agent rules in reproducing observed spatiotemporal crime distributions and offer new insights into the behavioral underpinnings of urban crime.

2 - Evaluating Police Patrol Strategies Through Agent-Based Modeling of Urban Crime

Yuan Zhou, University of Texas at Arlington, Arlington, TX, United States

Effective policing strategies require methods/tools that can simulate the dynamic relationship between law enforcement actions and criminal behavior in urban environments. An agent-based model (ABM) was developed to evaluate the impact of different police patrol strategies on the incidence and distribution of urban street crimes, including robbery, burglary, and larceny. The model integrates real-world data, such as crime statistics, environmental layouts, and census demographics, to construct a realistic simulation of urban mobility and routine activity. Two patrol strategies are implemented and tested: hotspot policing where officers are deployed to areas with historically high crime rates, and randomized patrols in which officers with general responsibilities dedicate a percentage of their time to high-crime areas. The ABM captures how offenders adapt their behavior in response to police presence, revealing how patrol tactics influence crime deterrence. Simulation results indicate that hotspot patrols can significantly reduce crime. This finding highlights the strengths and trade-offs of each strategy and underscore the potential of ABM as a decision support tool for law enforcement agencies seeking optimal patrol allocation strategies and crime prevention outcomes.

3 - Experimental Study of Vehicle Routing for a Police Patrolling Agent Based Simulation Model

Victoria Chen, The University of Texas-Arlington, Arlington, TX, United States, Shohreh Moradi, Darya Abbasi, Matine Ghasemloo, Jay Rosenberger, Yuan Zhou

Hot spots are patrol areas that have a high crime rate. Hot spot police patrolling has been studied in the criminal justice literature as an effective approach for reducing crime. Hot spot policing can be modeled via a vehicle routing optimization (VRO). The optimal route depends on the location and crime rate at hot spots. For an Arlington, Texas case study, robbery crime rates are simulated using an agent based model (ABM) based on crime theories to evolve criminal response to police patrol. The ABM simulation is computationally intensive. Rather than executing the ABM simulation many times to study the impact on VRO, a design and analysis of computer experiments approach is introduced to enable efficient study of the impact of different crime patterns on VRO solutions.

4 - An Integrated Mixed-Integer Programming Framework for Route Optimization and Maximum Coverage in Time-Dependent Patrol Scheduling

Jay Rosenberger, The University of Texas at Arlington, Arlington, TX, United States, Shohreh Moradi, Yuan Zhou, Victoria Chen

In this presentation, we tackle the challenge of optimizing police patrol routing by integrating real-time, time-dependent crime data into a dynamic, multi-visit scheduling framework that fully captures the spatial and temporal complexities of urban crime. Our approach is founded on a novel mixed-integer linear programming (MILP)

formulation that extends the classical vehicle routing problem by incorporating multiple visit indices per hotspot. This extension not only facilitates the determination of optimal spatial routes but also dynamically allocates patrol durations and schedules revisits based on evolving crime intensities. By directly linking activation decisions with routing constraints, our model ensures sequential, logical ordering of visits while adapting service times and revisit frequencies to meet operational demands. We evaluate the model performance using various instances and real-time datasets, demonstrating its capacity to continuously adjust patrol strategies in response to fluctuating hotspot conditions. The insights derived from our study yield actionable, adaptive multi-visit patrol schedules that enhance both the efficiency and responsiveness of policing in large, dynamic urban environments.

1 - Integrated Crop and Cargo War Risk Insurance: Application to Ukraine

Ismael Mohammad Pour, University of Massachusetts Amherst, Amherst, MA, United States, Anna Nagurney, Borys Kormych

Conflicts and wars can significantly disrupt global agricultural supply chains, with severe impacts on food security worldwide. War risk insurance, on the other hand, can mitigate farmers' losses. In this paper, we use the theory of variational inequalities to construct a new multicommodity international trade network equilibrium model with exchange rates on general transportation networks joining supply markets with demand markets under different wartime scenarios. The model incorporates capacities on production and transportation, as well as potential commodity losses in transportation. We then propose formulae for integrated crop and cargo war risk insurance premiums that are supply market and commodity specific and incorporate them into the model, along with government subsidies for the premiums. A series of numerical examples, both illustrative and algorithmically solved, focusing on the ongoing war on Ukraine, reveal the critical role of integrated war risk insurance and government support in sustaining agricultural commodity trade flows and supply market prices as well as protecting the revenue of farmers.

2 - Perishable Goods on a Roll: Optimizing Logistic Distribution Under Uncertainty Based on Remaining Shelf Life

Mauricio Gamez, Massachusetts Institute of Technology, Cambridge, MA, United States, Christopher Mejia, Thiago Serra

An important task in today's food industry is the control of product quality throughout the food supply chain. One of the main reasons that accelerates the spoilage of fresh food is disruptions in the supply chain network, such as poor food handling in facilities, transportation, packaging, and others. Models are needed to determine the optimal supply chain configuration to maintain food freshness and thus reduce food waste/loss. In this paper, freshness is integrated into the supply chain network by tracking the remaining shelf life. We formulate a mixed-integer linear programming (MILP) model under uncertainty that accounts for the disruptions along the logistics network. To model and solve this problem, we use two-stage stochastic programming and solve it with a sample average approximation (SAA) method. To accelerate the convergence of the algorithm, we have developed a rolling horizon heuristic that speeds up the performance of the model to obtain near-optimal solutions. The resulting model is applied in an illustrative case study and can be used for the planning and operation of food distribution systems considering freshness and cost. The results show that the proposed approach can achieve high quality solutions with guaranteed performance.

3 - Fortifying Distribution Network Nodes Subject to Different Disruption Levels

Bahar Çavdar, Rensselaer Polytechnic Institute, Troy, NY, United States, Pelin Kesrit, Joseph Geunes

We consider a distribution network for delivering a natural resource or physical good to a set of nodes, each of which serves a set of customers, in which flow disruptions may occur at one or more nodes. Each node receives flow via a path from one or more source nodes, implying that a node's service level depends on flow from upstream nodes. We consider the effects of disturbances of an uncertain degree of severity that can lead to reduced flow at individual nodes in the network, as well as fortification measures for protecting nodes against these disturbances. Our proposed model determines node fortification levels that maximize service availability under a limited budget and various assumptions on network structure, the nature of potential disturbances, and their associated probability distributions, which may be different at each node.

4 - Leveraging Decoupling in Robust Network Rebalancing

Andre Cire, University of Toronto, Toronto, ON, Canada, Aliaa Alnaggar, Adam Diamant

Many critical applications in resource sharing, humanitarian logistics, and healthcare can be modeled as two-stage distributionally robust optimization problems, where the second stage involves rebalancing supply across a network. For example, in healthcare systems, medical equipment or staff often must be reallocated in response to uncertain demand across hospitals. Existing methodologies for such problems are largely based on linear decision rules and heuristics, which can be suboptimal and computationally demanding for large-scale or highly uncertain environments.

In this work, we propose an exact approach for rebalancing problems with discrete, separable ambiguity sets, such as two-moment and polyhedral uncertainty sets. Specifically, we exploit an inherent decoupling property of the optimal second-stage network flow solutions to design a novel single-stage reformulation based on network models and decision diagrams. The resulting formulation is exponentially smaller than classical robust optimization models and enables new combinatorial separation techniques with stronger convergence.

We evaluate the approach using a real-world case of resource distribution in a hospital network, presenting optimal distributionally robust solutions for large-scale instances. In particular, we assess the value of optimality in identifying resilient yet less costly robust solutions, also comparing with traditional approaches such as linear decision rules.

5 - Multi-Objective Multi-Agent Coordination for Hurricane Preparedness and Response

Jessica Heier Stamm, Kansas State University, Manhattan, KS, United States, Ayesha Farooq

A multi-objective multi-agent coordination framework is presented, and its application is demonstrated using a case study approach for facility location and distribution in hurricane response. The framework integrates cooperative game theory and goal programming, enabling the evaluation of both operational and strategic aspects of humanitarian logistics. The analysis highlights that, with minor adjustments, fair distribution of costs and demands is attainable, emphasizing the stability and sustainability of inter-agency coordination. The framework ensures an equitable demand fulfillment across all affected areas while maintaining near-optimal cost efficiency for the responding organizations. Moreover, the analysis reveals that coordinated strategies, achieved through resource pooling among autonomous organizations, lead to a more effective network of facilities compared to independent actions. Overall, the findings suggest that integrated resource management not only enhances operational responsiveness and service levels in hurricane scenarios but also delivers superior returns on investment, offering valuable insights for policymakers and disaster response planners.

1 - How Much Data Do You Need? An Exact Characterization for Linear Optimization**Omar Bennouna, MIT, Cambridge, MA, United States**, Amine Bennouna, Saurabh Amin, Asuman Ozdaglar

We study the fundamental question of how informative a dataset is for solving a given decision-making task. In our setting, the dataset provides partial information about unknown parameters that influence task outcomes. Focusing on linear programs, we characterize when a dataset is sufficient to recover an optimal decision, given an uncertainty set on the cost vector. Our main contribution is a sharp geometric characterization that identifies the directions of the cost vector that matter for optimality, relative to the task constraints and uncertainty set. We further develop a practical algorithm that, for a given task, constructs a minimal or least-costly sufficient dataset. Our results reveal that small, well-chosen datasets can often fully determine optimal decisions—offering a principled foundation for task-aware data selection.

2 - Fast Revenue Maximization**Omar Besbes, Columbia University, New York, NY, United States**, Achraf Bahamou, Omar Mouchtaki

We study a data-driven pricing problem in which a seller offers a price for a single item based on demand observed at a small number of historical prices. Our goal is to derive precise evaluation procedures of the value of the historical information gathered by the seller, along with prescriptions for more efficient price experimentation. Our main methodological result is an exact characterization of the maximin ratio (defined as the worst-case revenue garnered by a seller who only relies on past data divided by the optimal revenue achievable with full knowledge of the distribution of values). This result allows to measure the value of any historical data consisting of prices and corresponding conversion rates. We leverage this central reduction to provide new insights about price experimentation. Motivated by practical constraints that impede the seller from changing prices abruptly, we first illustrate our framework by evaluating the value of local information and show that the mere sign of the gradient of the revenue curve at a single point can provide significant information to the seller. We then showcase how our framework can be used to run efficient price experiments. On the one hand, we develop a method to select the next price experiment that the seller should use to maximize the future robust performance. On the other hand, we demonstrate that our result allows to considerably reduce the number of price experiments needed to reach preset revenue guarantees through dynamic pricing algorithms.

3 - Active Exploration via Autoregressive Generation of Missing Data**Tiffany Cai, Columbia University, New York, NY, United States**, Hongseok Namkoong, Daniel Russo, Kelly Zhang

We pose uncertainty quantification and exploration in online decision-making as a problem of training and generation from an autoregressive sequence model, an area experiencing rapid innovation. Our approach rests on viewing uncertainty as arising from missing future outcomes that would be revealed through appropriate action choices, rather than from unobservable latent parameters of the environment. This reformulation aligns naturally with modern machine learning capabilities: we can i) train generative models through next-outcome prediction rather than fit explicit priors, ii) assess uncertainty through autoregressive generation rather than parameter sampling, and iii) adapt to new information through in-context learning rather than explicit posterior updating. To showcase these ideas, we formulate a challenging meta-bandit problem where effective performance requires leveraging unstructured prior information (like text features) while exploring judiciously to resolve key remaining uncertainties. We validate our approach through both theory and experiments. Our theory establishes a reduction, showing success at offline next-outcome prediction translates to reliable online uncertainty quantification and decision-making, even with strategically collected data. Semi-synthetic experiments show our insights bear out in a news-article recommendation task, where article text can be leveraged to minimize exploration.

4 - K-Svd with Gradient Descent**Yassir Jedra, Massachusetts Institute of Technology, Cambridge, MA, United States**, Emily Gan, Devavrat Shah

The emergence of modern compute infrastructure for iterative optimization has led to great interest in developing optimization-based approaches for a scalable computation of k-SVD, i.e., the $k \geq 1$ largest singular values and corresponding vectors of a matrix of rank $d \geq 1$. Despite lots of exciting recent works, all prior works fall short in this pursuit. Specifically, the existing results are either for the *exact-parameterized* (i.e., $k = d$) and *over-parameterized* (i.e., $k > d$) settings; or only establish local convergence guarantees; or use a step-size that requires problem-instance-specific oracle-provided information. In this work, we complete this pursuit by providing a gradient-descent method with a simple, universal rule for step-size selection (akin to pre-conditioning), that provably finds k-SVD for matrix of any rank $d \geq 1$. We establish that the gradient method with random initialization enjoys global linear convergence for any $k, d \geq 1$. Our convergence analysis reveals that the gradient method has an attractive region, and within this attractive region, the method behaves like Heron's method (a.k.a. the Babylonian method). Our analytic results about the said attractive region imply that the gradient method can be enhanced by means of Nesterov's momentum-based acceleration technique. The resulting improved convergence rates match those of rather complicated methods typically relying on Lanczos iterations or variants thereof. We provide an empirical study to validate the theoretical results.

Long-Term Expansion Planning of Power Systems with integrated complex systems

Invited Session

ENRE: Electricity

Chair: Enzo Sauma, Pontificia Universidad Catolica de Chile, Santiago, Chile

1 - Modeling Aging Processes in Bess to Assess the Impact on Power System Expansion Planning**Erick Ibacache, Pontificia Universidad Catolica de Chile, Santiago, Chile**, Enzo Sauma

The global energy transition has entailed the massive introduction of variable and intermittent renewable energy generation, which has exacerbated the challenges of maintaining the security and reliability of the power supply. Lithium-ion batteries, through BESS storage systems, have emerged as complementary alternatives to renewable energy by complementing the intermittency and variability of energy generation. However, this technology entails nonlinear and nonconvex storage capacity aging processes, making it difficult to study investment decisions in power system planning and operation models. This research proposes the incorporation of a BESS system aging through a storage capacity reduction function in an iterative MILP model for Power System Expansion Planning. The aging function is defined following the work by Johnen *et al.* (2021), considering the accumulative number of cycles for a BESS asset during the modeling horizon. The nonlinearity of the aging function is managed by applying a Piecewise linear approximation. The optimization model consists of two sub models, the first one taking into consideration investment decisions, and the other searching for the optimal operation. The model was evaluated in the Chilean Power System due to the line congestion and transmission challenges faced by the country, allowing for a more comprehensive analysis of the effects of aging and investment decisions for BESS assets. The results show that ignoring aging would overestimate the investment cost of BESS systems, but not the total installed capacity, resulting in a lower investment cost due to the delay in incorporating the asset into the Power System.

2 - Long-Term Power-System Expansion Planning Model Considering Battery Energy Storage Systems and Energy Storage in the Form of Hydrogen and/or Ammonia**Enzo Sauma, Pontificia Universidad Catolica de Chile, Santiago, Chile**

The accelerated capital cost reduction of battery energy storage systems (BESS) has set a new power-systems' paradigm. Something similar is occurring with Long-term Duration Energy Storage (LDES), such as energy storage in the form of hydrogen and/or ammonia. In this work, we propose a comprehensive long-term power-system expansion planning model, formulated as a Mixed-Integer Linear Program (MILP), to minimize investment and operational costs, while considering power-system technical constraints and including 2-hour and 4-hour duration BESS, as well as energy storage in the form of hydrogen and/or ammonia. The main finding derived from our results is that it is optimal, from a least-cost viewpoint, to have a mix of on-grid and off-grid energy storage capacity.

3 - Towards Exact Time Series Aggregation for Scalable Long-Term Power System Planning

Luca Santosuosso, Graz University of Technology, Graz, Austria, Sonja Wogrin

Achieving net-zero energy systems requires the large-scale integration of renewable energy sources, advanced flexibility technologies such as energy storage systems, and sector coupling. These developments substantially increase the complexity of long-term power system expansion planning models, which must now incorporate high-resolution input time series to accurately represent the variability of power generation, demand, and related system dynamics. Time series aggregation (TSA) is widely employed to manage this complexity; however, prevailing TSA methods rely on heuristic clustering techniques that prioritize capturing the statistical features of the input data over preserving the accuracy of the optimization model's outputs. Consequently, such TSA methods often undermine the practical applicability of the resulting aggregated models. The ERC-funded NetZero-Opt project introduces a paradigm shift in TSA by proposing a novel, performance-guaranteed clustering method grounded in Dantzig's simplex algorithm for linear programming. A key feature of this method is its ability to achieve substantial dimensionality reduction while preserving optimality exactly. Applied to an illustrative economic dispatch problem, the method compresses 8,760 hourly time steps into just three representative periods, without any loss of optimality. This breakthrough redefines TSA from a heuristic preprocessing tool into an exact, performance-guaranteed model reduction technique capable of alleviating the computational burden of large-scale, complex power system optimization models. This presentation will outline both the theoretical foundation and algorithmic implementation of the proposed TSA method, highlight its implications for computational tractability in long-term expansion planning, and discuss ongoing efforts to extend its guarantees to nonconvex and stochastic problem formulations.

4 - Modeling the Joint Expansion of Hydrogen and Power Infrastructure: a European Case Study

Miguel Carrion, Universidad de Castilla - La Mancha, Toledo, Spain, Rafael Zárate-Miñano, Carlos Merino

The transition to decarbonized power systems is one of the most complex challenges facing energy planners today. In this context, integrating green hydrogen into future energy systems may be a useful means of reducing greenhouse gas emissions in processes that are difficult to electrify. This work presents a generation capacity expansion model that optimizes the deployment of hydrogen infrastructure, including electrolyzers, compressors, storage systems, and pipelines. The model explicitly accounts for the costs of pipeline installation and compression, aiming to meet both hydrogen and electricity demands. To address the uncertainties associated with this problem, a stochastic programming approach is employed. A realistic case study based on the European continental energy system is used to test the proposed formulation. The results provide power- and hydrogen-related investment decisions by country, as well as inter-country flows of electricity and hydrogen.

5 - The Electrification Race: Probing The Power Grid/Data Center/Manufacturing Nexus

Jiyong lee, The University of Texas at Austin, Austin, TX, United States, Ilias Mitrai, Erhan Kutanoglu, Michael Baldea

The simultaneous development of artificial intelligence-related infrastructure, such as data centers, and the adoption of electrification technologies in the manufacturing sector necessitate a significant expansion of the power grid over a time horizon of several decades. To achieve economic competitiveness and guarantee that the power grid can satisfy the required demand, the investments across the different sectors must occur simultaneously, i.e., they must be coordinated. We develop a capacity expansion model to simultaneously determine the optimal investment policies for power grid expansion, construction of data centers, and adoption of electrification technologies in manufacturing. We consider the case of Texas - a hub for chemical and petrochemical manufacturing as well as data centers - and analyze optimal investment policies for different objectives (cost and green house gas emissions) and sources of uncertainty.

Multi-Time Scale Stochastic Optimization in Power Systems Planning and Operation

Invited Session

ENRE: Electricity

Co-Chair: Guzin Bayraksan, The Ohio State University, Columbus, OH, United States

Co-Chair: V Varagapriya, The Ohio State University, Columbus, OH, 43210, United States

1 - Bounds for Multi-Horizon Stochastic Optimization with Application to Power Generation and Transmission Expansion Planning

V Varagapriya, The Ohio State University, Columbus, OH, United States, Giovanni Micheli, Guzin Bayraksan, Francesca Maggioni

Multi-horizon stochastic optimization problems capture sequential decision-making under uncertainty across multiple time scales such as those including both strategic (long-term) and operational (short-term) scales. Due to the complexity arising from uncertainties across horizons, direct solution approaches become computationally prohibitive. We investigate computationally efficient methods to derive bounds on the optimal value of multi-horizon stochastic optimization problems, focusing on energy systems. We develop bounding techniques based on dissecting scenario trees over only strategic, only operational, and both strategic and operational scales. We show that each technique leads to a monotonic chain of lower bounds that approximate the optimal value of the original problem. Numerical results on a multi-horizon power systems generation and transmission expansion planning problem with renewable energy generation demonstrate the computational advantages of the proposed bounding methods using various dissection and recombination techniques on large-scale problems.

2 - Graph-Based Modeling and Decomposition of Multi-Scale and Hierarchical Optimization Problems

David Cole, Princeton University, Princeton, NJ, United States

Solving multi-time scale and hierarchical stochastic optimization problems can require specialized solution schemes that exploit problem structure. To capture structure in these problems, we introduce a graph-theoretic modeling framework implemented in the open-source package Plasmo.jl. This framework places variables, objectives, and constraints into nodes of a graph and places linking constraints on edges (for constraints with variables on two or more nodes). It also supports nesting graphs within other graphs to capture hierarchical relationships. These graph-based modeling capabilities provide an abstraction for modeling various stochastic programming problems in a universal way. We also introduce a generalized approach for exploiting these graph-structures using Benders decomposition and dual dynamic programming, as implemented in the package PlasmoBenders.jl. We give case studies in power systems showing how Plasmo.jl can be used for capturing problem structure, how these structures can be exploited using PlasmoBenders.jl, and how these principles extend to stochastic programming. Overall, the graph-based approach allows for capturing complex structure in large-scale optimization problems and provides a generalized abstraction for developing and implementing decomposition approaches.

3 - Market Enhancement Through the Progressive Introduction of Risk Instruments

Iman Khajepouradvani, University of Massachusetts at Amherst, Amherst, MA, United States, Golbon Zakeri, Geoffrey Pritchard, Daniel Ralph

Since uncertainties are inherent in different elements of the electricity market, such as demand, gas prices, the intermittency of renewable energies, etc. risk-averse market participants encounter unfavorable scenarios that affect both their risk exposure and their actions. This leads to an inefficient market, where the introduction of useful financial instruments can bring market closer to its optimal potential.

Building upon our previous work, we investigate to identify effective (and efficient) instruments that hedge market participants' risks and enhance the overall market structure.

4 - Climate-Resilient Nodal Power System Expansion Planning for a Realistic California Test Case

Amelia Musselman, Lawrence Livermore National Laboratory, Livermore, CA, United States

Climate change is increasingly impacting power system operations, not only through more frequent extreme weather events but also through shifts in routine weather patterns. Factors such as increased temperatures, droughts, changing wind patterns, and solar irradiance shifts can impact not only power system production and transmission but also electric load. The current power system was not designed to be resilient towards future climates. In this work, we aim to co-optimize power generation, storage, and transmission expansion in order to develop a climate-resilient system that is able to reliably meet future demands.

We analyze the impact of climate change on power systems via an adaptation of a capacity expansion planning model that seeks to minimize costs while ensuring power system resilience under a changing climate. We model the problem as a stochastic mixed-integer program, which we implement in Pyomo and solve using the stochastic programming library, mpi-sppy, along with Gurobi. We extend a synthetic but realistic, high-resolution, test case for California, the California Test System, to include parameters required for capacity expansion planning with climate scenarios. Leveraging climate data from the Energy Exascale Earth System Model, we map climate projections onto power system parameters, focusing on changes in temperature, wind speed, solar irradiance, and streamflow, which affect load and wind, solar, and hydro generation availability, respectively. We compare investment decisions based on present-day climate with future-climate and find that accounting for future climate scenarios significantly impacts generation, storage, and transmission investment decisions.

Prepared by LLNL under Contract DE-AC52-07NA27344.

5 - Methods for Multirate Scenario Generation

Harsha Gangammanavar, Southern Methodist University, Dallas, TX, United States

Decision-making under uncertainty at multiple timescales relies on an accurate representation and an ability to simulate scenarios from the underlying multi-rate stochastic process. This talk presents statistical methodologies to simulate time series data at a desired rate after observing observations at the highest rate. We present alternative approaches that involve estimating statistical models, simulating new time series using bootstrapping techniques, and subsampling. We report the results from our simulation study evaluating the empirical performance of these alternative methods.

1 - High-Resolution Electricity Grid Modeling for Smarter Power Planning, Emissions Tracking, and System Resilience in the United States

Braden Limb, Colorado State University, Fort Collins, CO, United States, Jason Quinn

Improving the spatial and temporal resolution of electricity grid models is critical for smarter planning, operations, and analytics in an increasingly complex energy system. Traditional emissions and electricity tracking methods report data at the balancing authority (BA) level, which obscures intra-regional variation and limits the effectiveness of data-driven decision-making.

This work presents a high-resolution modeling framework designed for sub-hourly, nodal-scale electricity tracking across the contiguous United States. The model is built on real-world substation, power generation, and transmission infrastructure, enabling accurate representation of how electricity moves through the physical grid.

Using locational marginal pricing (LMP) and power flow constraints, we simulate electricity generation, transmission, and associated emissions at over 3,500 nodes. Results reveal sharp intra-BA differences in power sources and grid constraints—for example, in Texas, renewable generation in the west faces bottlenecks delivering electricity to eastern demand centers. These insights enhance emissions accounting while also supporting broader applications such as siting analysis, grid resiliency assessment, and infrastructure investment planning.

By combining optimization, machine learning, and geospatial analytics, this platform enables utilities, system operators, and policymakers to make more informed decisions using granular, real-time data. While developed with emissions tracking in mind, the model's flexible architecture supports a wide range of operational research applications. It provides a powerful tool for analyzing electricity flows, evaluating system upgrades, and designing more adaptive, efficient energy systems—advancing smarter decisions for a better energy future.

2 - Synthesizing Representative Power Flow Datasets via Constrained Diffusion Models

Milad Hoseinpour Valoujaei, University of Michigan, Ann Arbor, MI, United States, Vladimir Dvorkin

Trustworthy machine learning (ML)-based optimal power flow (OPF) solvers requires access to large-scale and high-quality datasets. Real-world power flow data are often unavailable due to security and privacy concerns, making synthetic datasets a viable and secure alternative for developing ML models in power systems. This paper proposes a diffusion model to generate synthetic power flow datasets that preserve the statistical properties of the original data and satisfy relevant power flow constraints. To reduce training complexity and exploit domain structure, we introduce a variable-decoupling strategy that leverages the weak coupling between voltage magnitudes and active power, and between voltage angles and reactive power. Furthermore, we enforce feasibility during sampling via a gradient-guidance mechanism that steers the sampling path in a direction that minimizes the constraint violation. Numerical results demonstrate the effectiveness of our approach in producing high-fidelity and statistically representative synthetic power flow data.

3 - Integrating Conductor Health into Dynamic Line Rating and Optimal Power Flow Under Uncertainty

Geon Roh, Korea Institute of Energy Technology, Naju, Korea, Republic of, Jip Kim

The integration of carbon-neutral electricity sources faces challenges due to limited transmission infrastructure. Dynamic Line Rating (DLR) offers a promising solution by maximizing the utilization of existing transmission lines based on real-time weather data. However, transitioning to DLR introduces operational risks by pushing lines to their thermal limits. Furthermore, the impact of elevated temperature operation (ETO) on conductor health and maintenance is often overlooked.

To address these challenges, this paper 1) analyzes the risk structure in the existence of DLR and wind generation (WG) forecast errors and provides insights into power system operation, 2) models maintenance costs resulting from the ETO of overhead conductors, and 3) proposes a Conductor Health-Aware Adaptive Chance-Constrained Optimal Power Flow (CHAA-CCOPF) framework that accounts for both operational risks and the long-term costs associated with ETO.

The proposed model introduces two key enhancements to the OPF. First, chance constraints are employed to address uncertainties in DLR and WG forecasts using Gaussian mixture models and copulas. Second, maintenance costs due to hourly ETO are derived from a conductor Loss of Strength model using exponential modeling. These costs are expressed as a piecewise linear function and integrated into the objective function, with the conductor temperature distribution incorporated.

The model operates within an adaptive framework to enable periodic updates. Conductor state is updated every 24 hours using real-time operational data, while the computationally complex conductor temperature-current relationship is pre-fitted using day-ahead weather forecasts for the day-ahead dispatch.

4 - Kpg 193: a Synthetic Korean Power Grid Test System for Decarbonization Studies

Geonho Song, Korea Institute of Energy Technology, Naju, Korea, Republic of, Jip Kim

This paper introduces the 193-bus synthetic Korean power grid (KPG 193), developed using open data sources to address recent challenges of the Korean power system. The KPG 193 test system serves as a valuable platform for decarbonization research, capturing Korea's low renewable energy penetration, concentrated urban energy demand, and isolated grid structure. Clustering techniques were applied to preserve key system characteristics while maintaining computational tractability and representativeness. The system includes 193 buses, 122 generators, 407 transmission lines, and incorporates temporal weather datasets.

Its feasibility was validated through Unit Commitment (UC) and AC Optimal Power Flow (ACOPF) simulations using 2022 demand and renewable generation data. This test system aims to provide a foundational framework for modeling and analyzing the Korean power grid.

5 - Large-Scale Robust and Adaptive Planning for Generation and Transmission Expansion: California Case Study

Gabriel Mantegna, Princeton University, Princeton, NJ, United States, Emil Dimanchev, Neha Patankar, Jesse Jenkins

Electric utility planners and regulators must frequently make decisions about long-lived infrastructure under deep uncertainty surrounding cost, demand, and technology availability. However, most planning practitioners use scenario analysis alone for considering uncertainty, a planning process which can frequently miss out on infrastructure decisions that offer much greater flexibility and robustness to uncertainty. Methods exist for identifying robust and adaptive decisions in an optimization framework, but they have not yet been applied to the specific context of realistic-scale generation and transmission expansion planning. In this study we develop a method for applying two-stage adaptive robust optimization to realistic-scale generation and transmission expansion planning for the state of California, and demonstrate its advantages relative to today's deterministic planning practices.

6 - The Locational Marginal Value of Storage Under Risk of Disruption

Nathan Engelman Lado, Massachusetts Institute of Technology, Cambridge, MA, United States, Austin Saragih, Saurabh Amin

Electricity storage improves the resilience of distribution networks by supplying power during outages. Previous research has characterized the locational marginal value (LMV) of storage based on its use for electricity arbitrage and reducing line losses. However, the role of storage during outages, often a key driver of storage investments, remains underexplored in the theoretical literature. We fill this gap by explicitly incorporating outage probabilities into a stylized two-stage stochastic programming model. We model a profit-maximizing load-serving entity (LSE) that operates on a radial distribution network and whose profit is determined by its electricity purchases from the grid and sales to consumers. The LSE invests in storage and controls charge/discharge decisions subject to variations in demand, prices, and the risk of disruption.

We demonstrate that the LMV of storage differs across network locations, reflecting the ability of storage to reduce line losses when placed at each location. Moreover, we show that the LMV at each location varies depending on the distributions of prices, demand, and outage probability. Additionally, the cost of load shedding and outage probabilities significantly affect the LMV of storage. Through sensitivity analysis, we find that load shedding penalties that align retailer incentives with consumer losses are essential. Without appropriate incentives, increased outage risk can paradoxically lead to reduced storage investments, leaving consumers with less electricity. Our findings highlight the importance of explicitly considering outage conditions and incentives when planning distribution infrastructure investments, particularly as the risk of extreme weather events increases.

Co-Chair: Ana Dyreson, Michigan Technological University, Houghton, MI, United States

1 - Energy and Health Nexus: a County-Level Analysis of Power Outages in North Carolina

Rodrigo Mercado Fernandez, Loyola University Chicago, Chicago, IL, United States

This study explores the impacts of power outages on the rate of hospitalizations for various physical and mental health conditions in North Carolina. Using several years worth of power outage and health data, we merged the two datasets to quantify the impacts of power outages on household health. Our objective is to provide a comprehensive analysis of the impact of power outages on the health of North Carolina residents. We also aim to identify the most vulnerable populations during power outages. This study provides important insights for policymakers and stakeholders in the energy and healthcare sectors to address the impacts of power outages on household health.

2 - Climate-Resilient Planning of the Net-Zero European Energy System

Francesco De Marco, ETH Zürich, Zurich, Switzerland, Jacob Mannhardt, Alfredo Oneto, Giovanni Sansavini

The transition to a net-zero energy system depends heavily on variable renewable energy sources such as solar, wind, and hydroelectric power. While essential for decarbonization, these technologies are sensitive to climatic conditions, introducing new vulnerabilities—especially during extreme weather events like prolonged cold spells, droughts, and *Dunkelflaute* (periods of low wind and solar output). Climate-resilient planning under future climate uncertainty is therefore critical.

This study introduces a novel framework that combines System-Informed Scenario Reduction (SISR) with stochastic optimization to design energy systems resilient to climatic stress. The approach addresses two key challenges: (1) simplifying large climate datasets while retaining critical stress characteristics, and (2) incorporating climate uncertainty directly into optimization models.

Unlike traditional meteorological scenario selection, SISR uses energy system responses—via shadow price analysis—to identify stress events. A Wasserstein-distance-based clustering method reduces 60 climate scenarios to 5 representative ones, each reflecting unique stress patterns and assigned probabilities.

Applied to a net-zero European energy model, this framework produces cost-optimal solutions that are resilient to diverse climate scenarios. Compared to conventional single-scenario planning, it achieves equivalent resilience at an average of €14.8 billion lower cost. The analysis identifies two cost-resilience trade-off regions; in the high-resilience region, the marginal cost of resilience increases fivefold, yet remains economically favorable.

Notably, onshore wind combined with hydrogen storage emerges as the most cost-effective strategy for managing multi-day energy shortages. This work demonstrates how system-informed data reduction enables scalable stochastic optimization for climate-resilient infrastructure planning.

3 - Monash Energy: the Journey to Zero Carbon Transition

Terrence W.K. Mak, Monash University, Clayton, Australia

In this presentation, I will introduce how Monash University — the Monash Energy Institute and the Faculty of Information Technology, pave the way to zero carbon transition for the Australian and global communities.

In the first part of the talk, I will introduce major energy and grid challenges in Australia, and some of the latest solutions and options used by the energy and power system industry. How the Australian Government and the Australia Energy Market Operator visioned the future energy grid of Australia will be highlighted.

In the second part of the talk, I will introduce the vision, missions, areas of innovation, and major research contributions of the Monash Energy Institute. How the Institute impact Australia and the global community will be highlighted, and major partnerships will be presented. An introduction to the Faculty of Information Technology (IT), and how the theme of Sustainable Informatics contributes to net-zero emissions will also be discussed.

Finally, I will conclude the presentation with several interdisciplinary energy projects performed by our students at Monash University.

4 - Vehicle-to-Home Integration in Solar-Equipped Homes: Cost and Emissions Impacts Across the U.S

Jiahui Chen, University of Michigan Ann Arbor, Ann Arbor, MI, United States, Parth Vaishnav

Electric vehicles (EVs) and rooftop solar photovoltaics (PV) are both key pathways to a low-carbon energy future, but both face challenges. EV load growth strains utilities and power system operators, while rooftop solar adoption is limited by high upfront costs and declining compensation for exported energy. Vehicle-to-home (V2H) technology, which allows EVs to shift household load by charging when electricity is cheap and discharging when expensive, can turn EVs into demand flexibility assets. When combined with rooftop solar, V2H increases solar self-consumption and reduces reliance on export compensation. Consequently, homeowners will likely be less affected by changes in export energy compensation policies..

This study analyzes the cost and emissions impacts of V2H in solar-equipped homes across the U.S., under current and hypothetical billing schemes with reduced solar compensation. We account for local climate and regional differences in vehicle use (based on National Household Travel Survey data) when modeling EV energy consumption. EV charging and discharging are then optimized given EV driving demand, simulated household electricity load and simulated rooftop solar output (from ResStock database). We will compile realistic electricity price data and rooftop solar compensation rules for each region based on ratebooks and the US Utility Rate Database. As the dataset will likely be helpful to the building energy modeling community, it will be readily usable hourly time series data.

5 - Improving Rural Building Stock Modeling and Electricity Demand Projections Through Data Fusion and High-Resolution Inputs

Adnan Hilal, Michigan Technological University, Houghton, MI, United States, Ana Dyreson, Josh Quinnell, Dave Bohac, Chelsea Schelly

Electrification of heating loads on a national scale has received attention, but understanding the electrification potential and barriers in the rural north still poses a challenge. This challenge stems from the complex and dynamic relation between housing envelopes, heating demand, available energy resources, and winter and summer extremes. This study aims to inform future electrification and weatherization initiatives and to improve electricity demand modeling for electric power system resilience. A major obstacle to building energy modeling is the limited availability of high-quality, localized building data in these remote regions. This presentation focuses on data fusion to characterize single-family homes in rural Michigan, Wisconsin, and Minnesota. We integrate property assessor records, satellite imagery analyzed using machine vision techniques, and a custom housing survey to develop detailed, high-resolution inputs for ResStock, an open-source residential energy modeling platform developed by NREL. We present statistical comparisons that highlight key discrepancies between national default datasets (e.g., ResStock's baseline assumptions) and localized data sources, emphasizing the importance of using high-resolution inputs for rural modeling. We also illustrate how combining these sources enables the creation of more realistic archetype homes, which can better represent regional building stock for modeling efforts. This work represents an initial and necessary step toward modeling space heating demand in the rural north to assess the building stock's electrification resilience in cold climates. This work offers a new pathway for improving energy modeling accuracy in data-sparse regions, informs future electrification and weatherization planning, and addresses electricity resilience.

6 - Heat-Related Health Risks and Backup Power Benefits Under Extreme Weather and Power Outages

Shanshan Liu, University of Michigan, Ann Arbor, MI, United States, Parth Vaishnav

The concurrence of extreme weather events and power outages can critically challenge the availability of backup power, which is essential for operating medical equipment and maintaining safe indoor temperatures for vulnerable individuals. We employed a Reduced Complexity Building Energy Model (RC-BEM) to predict experienced indoor temperatures for residents in archetypal housing types. Simulations were conducted under various combinations of weather conditions and power supply scenarios (e.g., power on and power off) at the parcel level across 42 U.S. cities. Based on established associations between temperature and mortality risk, we assessed both the relative and absolute mortality risks for individuals. We then compared the reduction in health risks between scenarios with and without electric vehicles serving as backup power. Finally, by generating nationwide census block-level maps of vulnerability and under future climate scenarios, this study offers decisionmakers with insights to coordinate and allocate resources effectively.

7 - Evaluating Resilience of Power Sector Systems Against Deeply Uncertain Weather Futures

Vincent Carag, NREL, Golden, CO, United States

The rapid evolution of the U.S. energy sector has increased the importance of investing in power systems that are resilient to a large range of future weather conditions and events. Uncertainty in the characteristics and behavior of increasingly severe weather poses risks to the future stability and operation of the power systems that we build today. This research uses future load and renewable energy resource datasets including hydropower, wind, and solar downscaled from global climate model projections as inputs to the Regional Energy Deployment System (ReEDS), NREL's flagship capacity expansion model, to simulate the evolution of the U.S. bulk power system across multiple future weather conditions. This presentation demonstrates how the data is implemented to impact grid investments and resource adequacy contributions through the Probabilistic Resource Adequacy Suite (PRAS). Results show how future weather can impact future power sector investments and operating costs and performance, providing insights into robust investment strategies under deeply uncertain future weather conditions.

1 - The Impact of Batching Advanced Imaging Tests in Emergency Departments

Jacob Jameson, Harvard University, Cambridge, MA, United States, Soroush Saghaian, Robert Huckman, Nicole Hodgson, Joshua Baugh

Using detailed electronic health record data from two major U.S. emergency departments (EDs), we use practice variation across physicians to uncover the operational impact of discretionary batch ordering of imaging tests. Using causal inference approaches, we find that assigning an arriving patient to an ED physician who is a “batcher” versus a “sequencer” causally increases the patient's length of stay, time to disposition, and the number of imaging tests ordered. We find evidence that the impact of discretionary test batching on length of stay is heavily mediated by ordering additional imaging tests and the probability of being admitted to the hospital post-ED service. These findings suggest this ordering strategy may lead to clinical decision-making that introduces bottlenecks in patient flow. Conversely, sequencing imaging tests poses an “information gain” advantage compared to batching: the information obtained from a prior test allows for eliminating the need for ordering some future tests. Put together, our findings indicate that discretionary batch ordering may not be an optimal strategy for managing diagnostic imaging in emergency care and that interventions to reduce discretionary batch ordering may be warranted.

2 - The National Health Service Blended Payment Scheme: Incentive Issues and Optimal Reform

Sara Mohammadi, UCL School of Management, London, United Kingdom, Kenan Arifoglu, Bilal Gokpinar

The National Health Service (NHS) in England introduced the blended payment scheme for emergency care in 2019, as a mixed prospective payment model that combines fixed lump-sum payments under block contracts with variable activity-based payments under Payment by Results (PbR). Under this scheme, hospitals receive a fixed lump-sum payment at the start of the year based on their planned activity or readiness, and a variable payment at year-end that adjusts for differences between planned and actual activity, scaled by a variable rate but capped by break-glass provisions that limit extreme financial adjustment. We develop a game-theoretic model to analyze hospitals' treatment cost and planned activity decisions under the blended payment, considering information asymmetry between hospitals and regulator. Our analysis shows that while the blended scheme improves upon block contracts and PbR, it fails to fully align hospital incentives for cost reduction and readiness. We identify three

key limitations: (i) information asymmetry makes it difficult for the regulator to set the appropriate variable rate, (ii) break-glass provisions may weaken hospital incentives for readiness, and (iii) hospitals may face long-term budget deficits. To address these issues, we propose a modified blended payment that retains the fixed payment but reform the variable payment by: (i) setting the variable rate at 100%, (ii) adjusting payments based on deviations from average actual activity across hospitals rather than each hospital's own actual activity, and (iii) eliminating break-glass provisions. Our proposed payment model aligns hospital behavior with the social optimum and ensures a balanced long-term budget.

3 - Validating Counterfactual Estimations Under General Network Interference

Sadeh Shirani, Stanford University, Stanford, CA, United States, Mohsen Bayati, Yuwei Luo, William Overman, Ruoxuan Xiong

Randomized experiments are a cornerstone of data-driven decision making. Yet, their validity can be compromised by network interference, when a unit's treatment affects the outcomes of others. We argue that identifying population-level causal effects does not require recovering the full network structure; instead, it suffices to characterize how network interactions contribute to the evolution of aggregate outcomes. Building on this principle, we introduce the causal message-passing framework that investigates how outcomes evolve as the treatment propagates through the network, thereby extracting valuable information to compensate for missing network knowledge. We formalize this through state evolution equations that describe the dynamics of outcome distributions and establish a functional parallelism across treatment scenarios: while observed and counterfactual outcomes are different, both evolve under the same mathematical rules. This result yields a systematic method for counterfactual estimation and validation with consistency theoretical guarantees. To evaluate our framework, we introduce an interference gym, a suite of semisynthetic experiments spanning networks of AI agents, opinion formation in communities, and ride-sharing systems. Extensive evaluations demonstrate the robustness of our method across diverse interference structures. Finally, we delineate the theoretical limits of this approach, showing that strong temporal trends or unstable endogenous interference may undermine identification, particularly when interference patterns shift after treatment density crosses a critical threshold.

4 - Data-to-Dose: Personalized Dosing with Data Generation and Expert Feedback

Hansraj Satyam Verma, Carnegie Mellon University, Pittsburgh, PA, United States, Sridhar Tayur, Holly Wiberg, Shixiang Woody Zhu

Personalized treatment optimization is often constrained by data scarcity, especially in settings involving heterogeneous or rare patient profiles. Standard data-driven approaches struggle in these low-data regimes, limiting their ability to provide individualized and safe dosing recommendations. We introduce GenEx, a hybrid framework that integrates preference-based Bayesian optimization with a generative model that is fine-tuned using expert feedback. Expert-provided pairwise rankings guide updates to both a surrogate model and a generative component, which proposes synthetic data points in uncertain regions when the generator is consistent with expert preferences. Theoretical analysis establishes performance guarantees through sublinear regret bounds while controlling for bias introduced by synthetic augmentation. Numerical experiments simulating personalized dosing show that GenEx achieves faster convergence and improved decision quality compared to preference-only and purely generative baselines. Combining expert feedback with generative modeling can significantly improve personalized decision-making in healthcare and other data-limited contexts. This approach allows managers and clinicians to design more effective and safer individualized treatment plans while reducing the need for extensive historical data, and it offers a scalable strategy to efficiently integrate expert knowledge in practice.

The Interplay Between Learning, Optimization, and Statistics

Invited Session

OPT: Machine Learning

Chair: Lijun Ding, University of California San Diego, La Jolla, CA, United States

1 - On Squared-Variable Formulations

Lijun Ding, University of California San Diego, La Jolla, CA, United States

We revisit a formulation technique for inequality constrained optimization problems that has been known for decades: the substitution of squared variables for nonnegative variables. Using this technique, inequality constraints are converted to equality constraints via the introduction of a squared-slack variable. Such formulations have the superficial advantage that inequality constraints can be dispensed with altogether. But there are clear disadvantages, not least being that first-order optimal points for the squared-variable reformulation may not correspond to first-order optimal points for the original problem, because the Lagrange multipliers may have the wrong sign. Extending previous results, this paper shows that points satisfying approximate second-order optimality conditions for the squared-variable reformulation also, under certain conditions, satisfy approximate second-order optimality conditions for the original formulation, and vice versa. Such results allow us to adapt complexity analysis of methods for equality constrained optimization to account for inequality constraints. On the algorithmic side, we examine squared-variable formulations for several interesting problem classes, including bound-constrained quadratic programming, linear programming, and nonnegative matrix factorization. We show that algorithms built on these formulations are surprisingly competitive with standard methods. For linear programming, we examine the relationship between the squared-variable approach and primal-dual interior-point methods.

2 - Robustly Learning Single Index Models

Puqian Wang, University of Wisconsin, Madison, Madison, WI, United States, Nikolaos Zarifis, Jelena Diakonikolas, Ilias Diakonikolas

Single Index Models (SIMs) represent functions formed by composing an unknown univariate nonlinear activation σ with a linear map defined by an unknown vector w . The learning task—recovering both σ and w from i.i.d. labeled examples (x, y) , where y is a noisy evaluation of the SIM—leads to a nonconvex, often nonsmooth optimization problem, even for simple activation classes. SIMs are a fundamental model in supervised learning, capturing low-dimensional structure in high-dimensional data. While the setting with zero-mean bounded-variance noise has been well studied, more realistic formulations—where labels may deviate arbitrarily from any ground-truth SIM—are substantially more challenging. In particular, more relaxed notions of error and much stronger structural assumptions about both the activation and the distribution generating the data are required for computational tractability. Most provable guarantees in this regime have emerged only recently. In this talk, I will survey these developments and present a unifying optimization-theoretic framework based on local error bounds. These bounds capture how the gradient field remains meaningfully aligned with a target solution, thus providing a geometric “signal” that enables efficient learning with first-order methods, despite nonconvexity and noise.

3 - How Neural Networks Learn Features from Data, and How to Design Better Non-Neural Models in Practice

Daniel Beaglehole, UCSD, San Diego, CA, United States, Adityanarayanan Radhakrishnan, Enric Boix-Adserà, Mikhail Belkin

Inference from tabular data, collections of continuous and categorical variables organized into matrices, is a foundation for modern technology and science. Yet, in contrast to the explosive changes in the rest of AI, the best practice for these predictive tasks has been relatively unchanged and is still primarily based on variations of Gradient Boosted Decision Trees (GBDTs). Very recently, there has been renewed interest in developing state-of-the-art methods for tabular data based on recent developments in neural networks. In our work, we leverage insights into the mechanisms for feature learning in neural networks to design xRFM, a non-neural algorithm that combines feature learning kernel machines with a tree structure to scale to essentially unlimited amounts of training data.

On the TALENT benchmark, we show that compared to \$31\$ other methods, including recently introduced tabular foundation models (TabPFNv2) and GBDTs, xRFM achieves best performance across \$100\$ regression datasets and is competitive to the best methods across \$200\$ classification datasets outperforming GBDTs. Additionally, xRFM provides interpretability natively through the Average Gradient Outer Product.

Community Engagement, Resource Optimization, and New Innovations in Public Sector Operations Research

Invited Session

Public Sector OR

Chair: Carlos Morel Figueroa, Rensselaer Polytechnic Institute, 231 Congress St, Troy, NY, 12180, United States

Co-Chair: Weixiao Huang, Worcester Polytechnic Institute, Worcester, MA, 01609, United States

1 - Talk Math to Nonprofits: a Methodology to Capture Nonprofit Values into Optimization Models**Carlos Morel Figueroa, Rensselaer Polytechnic Institute, Troy, NY, United States, Weixiao Huang, Yunus Telli, Sarah Stanlick, Andrew Trapp, Jennifer Pazour**

While nonprofit organizations face challenges that can be addressed using optimization, mission-driven values complicate the use of traditional optimization-based decisions. Nonprofits must weigh these values alongside standard objectives, and at the same time understand and trust that the decisions align with community priorities. We introduce a methodology to assist optimization modelers integrate nonprofit stakeholder values into optimization models. The methodology outlines steps for identifying and incorporating multiple values, ensuring that stakeholder priorities are accurately represented. This process includes multiple stakeholder activities to collect feedback on both the interpretation of values and model outcomes.

We demonstrate this methodology with the SWAP system, a resource sharing platform piloted by Maryland-based nonprofits. SWAP facilitates resource exchanges through integer optimization. We developed five optimization models, each addressing different nonprofit values. The output of these models were presented to nonprofit stakeholders to explore how differing stakeholder priorities influence resource exchanges. Stakeholders also provided feedback on the outputs they found most useful and the values they prioritize. This case study demonstrates how stakeholder values influence decision-making in nonprofit resource exchanges and shows the practical utility of our proposed framework.

2 - Developing Optimization Models with Cognitive Systems Engineering**Emily Tucker, Clemson University, Clemson, SC, United States, Tyler O'Brien, Steven Foster, Sudeep Hegde**

One goal of applied operations research is to improve decisions in practice. For an optimization model to be useful, the underlying problem must be understood, the formulation representative, the data appropriate, and the model's recommendations understood by the decision-makers. Current approaches for developing optimization models primarily rely on past experience, rather than underlying theory, to guide decisions on how to include stakeholders in the process. In this present, we present a new framework for applied optimization modeling with stakeholders. In each iteration, modelers develop model versions based on their current mental models of the decision process; these mental models are progressively updated based on interviews with stakeholders and thematic analyses. Stakeholders' mental models may also update as the model versions and the context change. The theoretical foundation is based on methodologies from the field of Cognitive Systems Engineering that focus on understanding emergent patterns based on systems, stakeholders, and environments. We apply the framework to a case study of locating hand sanitizer stations at a large academic institution.

3 - Considerations for Modeling and Defining Effective Interventions into Sex Trafficking**Thomas Sharkey, Clemson University, Clemson, SC, United States, Vanessa Voller, Tonique Ayler, Kelle Barrick, Teresa Forliti, Joy Friedman, Daniel Lopes da Silva, Kayse Maass, Lauren Martin, Mikki Mariotti, Christine Nelson, Yongjia Song**

Interventions designed to disrupt sex trafficking and the harm that it causes often have a goal in mind. We present considerations necessary to build models of interventions into sex trafficking and measure their effectiveness. These considerations blend existing frameworks, such as the 3P paradigm and public health approaches, with survivor-centered expertise to ensure a well-rounded perspective. We then discuss how past OR work into sex trafficking fits within these considerations and how incomplete, potentially unreliable, data influences this past work.

4 - Fairness-Efficiency Symbiosis**Violet (Xinying) Chen, Stevens Institute of Technology, Hoboken, NJ, United States, David Rea**

Ensuring algorithmic decisions induce fair solutions is of critical societal importance. Much has been written about the potential tradeoff between fairness and efficiency in worst case scenarios. Simultaneously, there is growing empirical evidence that the fairness-efficiency tradeoff is often avoidable in practice. This research seeks an understanding for when fairness and efficiency can form a symbiotic relationship, i.e., when both can be improved simultaneously. Based on the distributive justice framework, we distinguish between two fairness perspectives: equity seeks outcomes proportional to recipients' merit or needs, while equality seeks the same outcomes for all. We provide simple formulas for understanding when (a) fairness will be symbiotic with efficiency, and (b) equity will be more efficient than equality and vice versa. A core component in our formulas links symbiosis patterns with the alignment among efficiency, equity and equality. Specifically, given an efficient decision, we show that making the decision more equitable can improve efficiency (i.e., a symbiotic relationship between equity and efficiency), whereas seeking better equality will almost always result in a tradeoff with efficiency.

5 - Equity in Hunger Relief**Naurin Zoha, University of Michigan, Ann Arbor, MI, United States, Julie Ivy, Tanzid Hasnain**

Food insecurity refers to a lack of access to sufficient food for an active, healthy life. In 2023, 13.5% of households in the USA experienced food insecurity. Studies show that hunger does not affect everyone equally, with persistent disparities in food insecurity levels among different demographic groups. Food banks aim to serve these populations equitably. While previous research has focused on geographic equity—ensuring food distribution aligns with regional demand—there is a growing shift toward demographic equity, which addresses disparities among groups based on race and ethnicity, age, gender, family composition etc. This study aims to develop a multi-criteria deterministic linear programming model that incorporates both geographic and demographic equity using various equity measures. It explores the impact of these measures on food bank operations while also considering effectiveness (minimizing undistributed food) and efficiency (minimizing distribution costs). The model is then applied to a real food bank network to derive optimal policies for equitable allocation across demographic groups and geographic regions.

Chair: Thomas Robbins, East Carolina University, Greenville, NC, United States

1 - Scheduling An ACC Women's Basketball Season**Kevin Hutson, Furman University, Greenville, SC, United States**

The Atlantic Coast Conference expanded to eighteen teams last year with the inclusion of three new teams, two of which reside in California. This greatly increased the amount of conference travel for league teams and brought about difficult match-up scenarios like cross-country Thursday/Sunday road games against the league's top teams. In this talk we explore scheduling options for the league to balance the competing objectives of minimizing travel costs, including environmental impact, with creating a fair schedule. We also consider many of the desired constraints from the league such as venue availability, television-network-desired matchups, etc. in the model.

2 - Adding New and Entertaining sports from the Ancient Olympics to Los Angeles 2028 and Adding An Esports Olympics**Raymond Stefani, California State University Long Beach, Lake Forest, CA, United States**

Relevant and entertaining sports have been added throughout Olympic history. Beginning in 776 BC with one running event, athletics in the Ancient Olympics involved 49% of all events. Combat sports like boxing and wrestling (32%) began in 708 BC, chariot racing (11%) began in 680 BC, equestrian events (4%) began in 648 BC, while in 396 BC artistic events (4%) like acting and lyre playing were added. Although women competed in their own Heraea Games, 6 women officially won 8 Olympic equestrian and chariot events, by owning the winning horses. The 1896 marathon linked ancient with modern. Women began competing in 1900. From 1896-1936, host nations, with IOC approval, selected sports that maintained relevance and entertainment. After WW2, locally interesting non-medal demonstration sports were contested from 1948-1992. Six of those became continuing core sports: badminton, baseball, handball, judo for women, taekwondo, and tennis. Six sports were added directly to continuing status: archery, judo for men, softball, table tennis, triathlon, and volleyball. From 2004 to 2016, trying to limit sports federations to 28, baseball and softball were dropped and golf and rugby 7s replaced them. Under Olympic Agenda 2020, Tokyo 2020 added skateboarding, sport climbing, surfing, karate, baseball, and softball. Paris 2024 included skateboarding, sport climbing and surfing, which the IOC then made continuing core sports. Eclectic breakdancing was also included. The Los Angeles 2028 Olympics will add baseball, softball, lacrosse, cricket, squash, and flag football. The IOC plans an Olympic Esports Games starting in 2027 in Saudi Arabia.

3 - Brains OR Legs: How to Organize a Fair Rogaining Competition?

Dries Goossens, Ghent University, Gent, Belgium, David Van Bulck, Joonas Pääkkönen, Benjamin Jacquet

Rogaining is an orienteering running sport where participants need to decide what control points to visit and in which order. The objective is to collect the largest possible score associated with the visited controls, without violating the time limit. While extensive literature exists on the orienteering problem from a participants' point of view, there is limited understanding of how to design a rogaining contest where physical abilities do not dominate over cognitive skills in influencing the race outcome. To create these contests, we propose a heuristic bilevel optimization approach where at the upper level organizers assign scores to candidate control points, while at the lower level participants solve the classic orienteering problem. The simulation of the selected courses by the participants results in a provisional ranking which allows to evaluate the score assignment as determined by the organizer at the upper level. We apply our methodology to the 2023 World Rogaining Championships, demonstrating the necessity of thoughtful score allocation to ensure a balanced emphasis on both skills.

4 - Does the Elo Model Work for Team sports?

Thomas Robbins, East Carolina University, Greenville, NC, United States

The Elo model is a ranking model initially designed to rank chess players that has been extended to a number of individual and team sports. In this talk we review the Elo model and investigate its usefulness in short season competitive environments.

5 - Stuck in Limbo: Evaluating Post-Shot Behavior in College Basketball

Tristan Robbins, University of Florida, Orlando, FL, United States

This project introduces and explores the concept of "limbo," a critical yet often overlooked moment in college basketball when players hesitate or remain idle after a missed shot from their team. When a player is stuck in limbo, they do not crash the offensive boards and they do not retreat to defend against the opposing team's transition, instead they stand near-motionless, seemingly shot admiring. Through analyzing and evaluating game film from the University of Florida's men's basketball team, this research categorizes post-shot decisions into three outcomes: initiating offensive rebound attempts, retreating defensively, or being stuck in limbo. The main objective of this project is to quantify how each individual players' post-shot decision affects second-chance points and transition defense. Using data gathered from film analysis, regression models were constructed to evaluate the impact of these behaviors on an overall team outcome. Overall results suggest that even small reductions in players stuck in limbo on a possession-by-possession basis can significantly improve defensive performance in transition without hindering success in offensive rebounding. By assigning value to split-second decisions following missed shots, this project provides a framework that coaching staffs can use to adjust player tendencies and refine strategy. Overall, this work contributes to the broader field of basketball analytics by offering a fresh new lens on evaluating post-shot decisions.

Learning and Optimization under Uncertainty: Algorithms and Applications

Invited Session

OPT: Optimization Under Uncertainty

Chair: Jiajin LI, The University of British Columbia, Vancouver, BC, Canada

1 - On the Uniform Convergence of Subdifferentials in Stochastic Optimization and Learning

Feng Ruan, Northwestern University, Evanston, IL, United States

We investigate the uniform convergence of subdifferential mappings from empirical risk to population risk in nonsmooth, nonconvex stochastic optimization. This question is key to understanding how empirical stationary points approximate population ones, yet characterizing this convergence remains a fundamental challenge. This work establishes a general reduction principle: for weakly convex stochastic objectives, we show that a uniform bound on the convergence of selected subgradients—chosen arbitrarily from subdifferential sets—yields a corresponding uniform bound on the Hausdorff distance between the subdifferentials over any open subset of the domain. This deterministic result reduces the study of subdifferential convergence to simpler vector-valued subgradient convergence. We apply this reduction to derive sharp uniform convergence rates for subdifferential mappings in stochastic convex-composite optimization, without relying on differentiability assumptions on the population risk. These guarantees clarify the landscape of nonsmooth empirical objectives and offer new insight into the geometry of optimization problems in robust statistics and related settings.

2 - Population-Proportional Preference Learning from Human Feedback

Jiawei Zhang, MIT, Cambridge, MA, United States

Conventional preference learning methods often prioritize majority opinions when aggregating preferences from multiple evaluators, resulting in policies that underrepresent minority groups. To address this limitation, we introduce a novel preference learning framework designed to align policies proportionally with the true population distribution of evaluator preferences. Our approach infers a feasible set of evaluator population shares directly from pairwise comparison data. Using these estimates, the algorithm constructs a policy that satisfies foundational axioms from social choice theory, namely monotonicity and Pareto efficiency, along with our newly introduced axioms of population-proportional representation and population-bounded strategyproofness, which existing methods fail to meet. Additionally, we propose a softmax relaxation method that smoothly balances population-proportional representation with the selection of the Condorcet winner. Finally, we validate the effectiveness and scalability of our approach through experiments on both tabular recommendation tasks and large-scale language model alignment.

3 - Gradient Descent with Adaptive Stepsize Converges (Nearly) Linearly Under Fourth-Order Growth

Liwai Jiang, Purdue University, West Lafayette, IN, United States

A prevalent belief among optimization specialists is that linear convergence of gradient descent is contingent on the function growing quadratically away from its minimizers. In this work, we argue that this belief is inaccurate. We show that gradient descent with an adaptive stepsize converges at a local (nearly) linear rate on any smooth function that merely exhibits fourth-order growth away from its minimizer. The adaptive stepsize we propose arises from an intriguing decomposition theorem: any such function admits a smooth manifold around the optimal solution—which we call the ravine—so that the function grows at least quadratically away from the ravine and has constant order growth along it. The ravine allows one to interlace many short gradient steps with a single long Polyak gradient step, which together ensure rapid convergence to the minimizer. We illustrate the theory and algorithm on the problems of matrix sensing and factorization and learning a single neuron in the overparameterized regime.

4 - Set Smoothness Unlocks Clarke Hyper-Stationarity in Bilevel Optimization

He Chen, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Jiajin LI, Anthony Man-cho So

Solving bilevel optimization (BLO) problems to global optimality is generally intractable. A common alternative is to compute a hyper-stationary point—a stationary point of the hyper-objective function formed by minimizing/maximizing the upper-level function over the lower-level solution set. However, existing approaches either yield weak notions of stationarity or rely on restrictive assumptions to ensure the smoothness of hyper-objective functions. In this paper, we remove these impractical

assumptions and show that Clarke hyper-stationarity is still computable even when the hyper-objective is nonsmooth. Our key tool is a new structural condition, called set smoothness , which captures the variational relationship between the lower-level solution set and the upper-level variable. We prove that this condition holds for a broad class of BLO problems and ensures weak convexity (resp. concavity) of pessimistic (resp. optimistic) hyper-objective functions. Building on this, we show that a zeroth-order algorithm computes approximate Clarke hyper-stationary points with a non-asymptotic convergence guarantee. To the best of our knowledge, this is the first computational guarantee for Clarke-type stationarity for nonsmooth hyper-objective functions in BLO. Our developments, especially the set smoothness property, contribute to a deeper understanding of BLO computability and may inspire applications in other fields.

OPT: Optimization Under Uncertainty

Chair: Afroz Jalilzadeh, The University of Arizona, Tucson, United States

Co-Chair: Erfan Yazdandoost Hamedani, The University of Arizona, Tucson, AZ, United States

1 - Simultaneous Learning and Optimization for Misspecified Saddle Point Problems

Mohammad Mahdi Ahmadi, University of Arizona, Tucson, AZ, United States, Erfan Yazdandoost Hamedani

In this talk, we study a class of saddle point (SP) problems where part of the objective depends on an unknown (misspecified) parameter that must be learned through a secondary optimization task. Such problems arise in many applications, including portfolio optimization, inventory control, and power systems, where model uncertainty plays a key role. To address this challenge, we adopt a simultaneous approach that interleaves learning and optimization at each iteration, rather than solving them sequentially. This integrated framework introduces new analytical and algorithmic challenges due to the evolving nature of the learned parameter.

We extend accelerated primal-dual (APD) algorithms proposed by Hamedani and Aybat (2021) for the considered misspecified setting. Our methods are designed to efficiently handle the coupling between the two optimization tasks, with one of them enabling an adaptive backtracking line search. We establish convergence guarantees for the proposed algorithms and demonstrate their performance through numerical experiments. The results highlight the benefits of solving optimization problems jointly and demonstrate the superiority of our algorithms in effectively handling misspecified saddle point problems.

2 - Nonconvex Semi-Infinite Constrained Min-Max Optimization

Cody Melcher, The University of Arizona, Tucson, AZ, United States, Erfan Yazdandoost Hamedani, Afroz Jalilzadeh, Zeinab Alizadeh, Lindsey Hiett

In this talk, we consider a class of nonconvex min-max optimization problems with infinite constraints, motivated by applications such as adversarial robustness and safety-constrained learning. While semi-infinite programming offers a natural framework for these problems, its theoretical development in the nonconvex setting is still limited. We propose a novel inexact dynamic barrier primal-dual algorithm and show that, assuming the Lojasiewicz inequality holds for the infeasibility residual function, the method converges to an approximate KKT solution. Finally, we present several numerical experiments on robust multitask learning with task priority to demonstrate the practical performance of our approach.

3 - Solving Stochastic Quasi-Variational Inequality Problems

Zeinab Alizadeh, university of arizona, Tucson, AZ, United States, Afroz Jalilzadeh

While Variational Inequality (VI) is a well-established mathematical framework that subsumes Nash equilibrium and saddle-point problems, less is known about its extension, Quasi-Variational Inequalities (QVI). QVI allows for cases where the constraint set changes as the decision variable varies allowing for a more versatile setting. Although deterministic and stochastic QVIs have received growing attention, existing methods almost invariably require strong monotonicity, which severely restricts their practical applicability. In this talk, we relax that requirement and introduce algorithms that work under much weaker conditions, like non-strongly monotone operators, then illustrate their power through real-world applications and numerical experiments highlighting both stability and convergence.

4 - An Intuitive Algorithm for Two-Stage Distributionally Robust Optimization

Zhengsong Lu, University of Pittsburgh, Pittsburgh, PA, United States, Bo Zeng

Distributionally robust optimization (DRO) has been adopted in many practical systems (e.g., power, logistics, and healthcare) to support their design, operations, and reliability. In this talk, we take a primal perspective to analyze DRO and directly utilize its structure to develop intuitive and efficient computational algorithms. The resulting column-and-constraint generation method and its variants are simple and application-friendly, often outperforming existing approaches. Numerical results will be presented.

Recent Advances in Solution Methods for Conic Optimization

Invited Session

OPT: Linear and Conic Optimization

Chair: Pouya Sampourmahani, Lehigh University, Bethlehem, PA, United States

1 - Faster High-Accuracy Algorithm for Multi-Commodity Flow

Jan van den Brand, Georgia Tech, Atlanta, GA, United States

In this talk, we will see that graph techniques can speed up algorithms for solving fractional multi-commodity flow to high accuracy.

Since the development of efficient linear program solvers in the 80s, all major improvements for solving fractional multi-commodity flows came from improvements to general linear program solvers rather than graph techniques. This phenomenon sparked research to understand why graph techniques are unlikely to help with multi-commodity flows. Evidence was given by [Ita'79 and Ding-Kyng-Zhang'22], showing that solving multi-commodity flow is equivalent to solving general linear programs, thus one would not expect graph techniques to help.

However, these equivalence reductions create sparse graphs, so improvements to multi-commodity flows on denser graphs might exist.

In this talk, we will see that one can indeed speed up multi-commodity flow algorithms on non-sparse graphs via graph techniques, demonstrating that the problem is more combinatorial in nature than previously thought. In particular, we show that k -commodity flow on an n -vertex m -edge graph can be solved in $\tilde{O}(k^{2.5}\sqrt{m}n^{\omega-1/2})$ time.

2 - Near-Optimal Path Following in the L_2 Neighborhood

Bento Natura, Columbia University, New York City, NY, United States

We investigate a variant of the trust region interior point method (TR-IPM) which was originally given by Lan, Monteiro and Tsuchiya (SIAM J. Optim. 2009). We show that the iteration complexity of this algorithm is essentially optimal in the l_2 -neighbourhood of the central path. Namely, the iteration complexity of the TR-IPM is upper bounded by the minimum number of segments of any piecewise linear curve traversing in a close l_2 -neighborhood of the central path.

This strengthens the previous bounds that were in terms of the Dikin--Todd--Stewart conditional number of the constraint matrix. In particular, it improves the universal bound given by Allamigeon et al. (SIAM J. Comput. 2025) by $O(n^{1.5} \log n)$ when in the l_2 -neighborhood. In particular, it matches the iteration complexity of any such existing IPMs which also have direct dependence on the problem dimension and the Dikin-Todd-Stewart conditional number of the constraint matrix.

Lan, Monteiro and Tsuchiya only gave a weakly polynomial algorithm for solving the trust region problem, and left it as an open question to develop a strongly polynomial algorithm. We resolve this question by presenting a new strongly polynomial algorithm that solves a parametric minimum norm problem to very high accuracy. As a result, each iteration of our TR-IPM can be implemented in strongly polynomial time. Our algorithm for the parametric problem relies on approximately computing the singular value decomposition of an associated matrix. These singular values enable us to locate the optimal parameter value in a narrow interval, where Newton's method exhibits quadratic convergence.

3 - Acceleration Meets Inverse Maintenance: Faster ℓ_{∞} -Regression

Shunhua Jiang, Columbia University, New York, NY, United States

We propose a randomized multiplicative weight update (MWU) algorithm for ℓ_{∞} regression that runs in $\tilde{O}(n^{2+1/22.5} \text{poly}(1/\epsilon))$ time when $\omega = 2 + o(1)$, improving upon the previous best $\tilde{O}(n^{2+1/18} \text{poly}(\log(1/\epsilon)))$ runtime in the low-accuracy regime. Our algorithm combines state-of-the-art inverse maintenance data structures with acceleration. In order to do so, we propose a novel acceleration scheme for MWU that exhibits stability and robustness, which are required for the efficient implementations of the inverse maintenance data structures.

We also design a faster deterministic MWU algorithm that runs in $\tilde{O}(n^{2+1/12} \text{poly}(1/\epsilon))$ time when $\omega = 2 + o(1)$, improving upon the previous best $\tilde{O}(n^{2+1/6} \text{poly}(\log(1/\epsilon)))$ runtime in the low-accuracy regime. We achieve this by showing a novel stability result that goes beyond previously known works based on interior point methods (IPMs).

Our work is the first to use acceleration and inverse maintenance together efficiently, finally making the two most important building blocks of modern structured convex optimization compatible.

4 - Cuhallar: a Gpu Accelerated Low-Rank Augmented Lagrangian Method for Large-Scale Semidefinite Programming

Jacob Aguirre, Georgia Institute of Technology, Atlanta, GA, United States, Diego Cifuentes, Vincent Guigues, Renato D C Monteiro, Victor Hugo Nascimento, Arnesh Sujanani

This paper introduces cuHALLaR, a GPU-accelerated implementation of the HALLaR method proposed in prior work for solving large-scale semidefinite programming (SDP) problems. We demonstrate how our Julia-based implementation efficiently uses GPU parallelism through optimization of simple, but key, operations, including linear maps, adjoints, and gradient evaluations. Extensive numerical experiments across three problem classes—maximum stable set, matrix completion, and phase retrieval show significant performance improvements over both CPU implementations and existing GPU-based solvers. For the largest instances, cuHALLaR achieves speedups of 30-140x on matrix completion problems, up to 135x on maximum stable set problems for Hamming graphs with 8.4 million vertices, and 15-47x on phase retrieval problems with dimensions up to 3.2 million. Our approach efficiently handles massive problems with dimensions up to $(n,m) \approx (8 \times 10^6, 3 \times 10^8)$ at 10^{-5} relative precision, solving matrix completion instances with over 8 million rows and columns in just 142 seconds. These results establish cuHALLaR as a very promising GPU-based method for solving large-scale semidefinite programs.

5 - Advances in Interior-Point Methods for Hyperbolic Programming

Mehdi Karimi, Illinois State University, Normal, IL, United States, Levent Tuncel

Hyperbolic programming is a class of convex optimization problems that has been extensively studied from a theoretical perspective, particularly in connection with the generalized Lax conjecture. Although it generalizes semidefinite programming and the hyperbolicity cone admits a well-defined self-concordant barrier (making it a natural candidate for interior-point methods), there is currently no (as far as we know) general-purpose solver available for hyperbolic programs, apart from our software package, Domain-Driven Solver (DDS). Motivated by growing interest in the practical applications of hyperbolic programming, we have made several significant improvements to DDS, enabling it to solve larger and more diverse problems. Additionally, we introduce a new library of benchmark problems designed to support the development and evaluation of hyperbolic programming solvers.

1 - Modeling Liquidity and Survival: Inventory Speculation and Bankruptcy Risk Analysis

Tonghua Lin, Rutgers University, Harrison, NJ, United States, Weiwei Chen, Xiaowei Xu

This study investigates a financial inventory management problem where firms must allocate limited cash and inventory resources under market uncertainty. When market conditions are volatile, excessive inventory may erode liquidity and increase the risk of bankruptcy. We propose a stochastic approach to model firm decision-making that prioritizes survival over profit, capturing key trade-offs between inventory replenishment and liquidation. By framing bankruptcy as a critical constraint, this leads to a multi-period, multi-objective extension of the classical newsvendor problem. The study offers a new perspective on resource allocation strategies for firms facing financial and operational pressures. We further develop a stochastic optimization model based on a Markov Decision Process (MDP) framework, proving the existence of an optimal policy and validating its effectiveness through numerical experiments. The findings provide theoretical and practical insights into how firms can improve resilience through liquidity-aware planning, especially in industries vulnerable to demand and price shocks.

2 - Enhancing Dialysis Center Resilience: Strategic Integration of Contract Clinicians and Support Staff

Chenhao Zhou, Rutgers University, Edison, NJ, United States, Tonghua Lin, Xin Ding, Weiwei Chen

Facing chronic labor shortages, U.S. dialysis providers increasingly fill critical roles with agency personnel, creating *fissured* teams. *Clinicians*—registered nurses and physicians—make treatment decisions and supervise care, whereas *support staff*—licensed practical/vocational nurses (LPNs/LVNs) and patient-care technicians (PCTs)—carry out routine tasks under that supervision. Organizational learning hinges on time-in-place: clinicians who repeatedly work at the same facility accumulate tacit process knowledge, whereas agency clinicians divide their effort across multiple sites, limiting repetition and weakening local know-how.

Drawing on the knowledge-based view and learning-by-doing theory, we compile a 2015-2023 facility-year panel that links CMS staffing reports to quality and cost-efficiency metrics for 7,000s dialysis clinics. Using IV-2SLS estimation, we quantify how the share of hours worked by agency clinicians—our measure of workforce fissuring—affects facility performance. We then examine whether stability among support staff moderates any performance penalty and whether this moderation is stronger when task interdependence is high (broad delegation scope, complex case-mix).

By framing fissured staffing as an operations-design challenge grounded in time-dependent learning, the study offers actionable guidance: maintain labor flexibility at the clinician tier but anchor institutional memory through consistent support teams. The resulting rule of thumb helps healthcare and other knowledge-intensive services balance agility with the retention of critical capabilities.

3 - A Predictive Model for Hospital-Acquired Pressure Injuries (Hapi) to Enhance Healthcare Service Quality

Xinyi Huang, University of Iowa, Iowa City, IA, United States, Bang An, Weiguo Fan, Ling Tong

Hospital-acquired pressure injuries (HAPI) pose a significant risk to Intensive Care Unit (ICU) patients, with existing assessment tools like the Braden Scale often lacking accuracy. Traditional machine learning models struggle with time-variant features, leading to loss of critical information. This study introduces a novel dual-view machine learning framework that leverages electronic health records and a deep recurrent neural network to learn from both time-variant and time-invariant features separately. The proposed method achieves a prediction accuracy of 93.37% and a recall of 41.81%, with a 30% average improvement in precision over baseline models. These results demonstrate improved HAPI risk assessment, enabling earlier and more accurate identification of at-risk patients. By facilitating timely and targeted interventions, this model supports enhanced quality of care and improves the overall service patients receive in critical care settings.

4 - Privacy Shields: a Game-Theoretic Analysis of Competing Platforms' Incentives to Adopt Protection Technologies in the Presence of Data Brokers

Min Zhang, Communication University of China, Beijing, China, People's Republic of, Zhiyong Li, Hongxin Liu

Data-intensive platforms face a triple pressure of increasing consumer privacy demands, tightening regulations (e.g., the massive fines on Meta and Twitter), and market competition, urgently necessitating a balance between data utilization and privacy compliance. This study uses an analytical game-theoretic model to investigate the privacy protection technology adoption strategies of competing platforms. We find that when the unit price of consumer's recorded data by data brokers is too low (high), neither (both) competing platform adopts the privacy protection technologies; when the unit price of consumer's recorded data by data brokers is medium, competing platforms adopt asymmetric privacy protection strategies (i.e., only one platform adopts the privacy protection technology). Interestingly, when the unit price of consumer's recorded data by data brokers is medium, neither platform adopting privacy protection technology is a prisoner's dilemma situation. Finally, we find when the unit price of consumer's recorded data by data brokers is too high, both platforms adopting privacy protection technologies is a win-win result for platforms and consumers. However, when the unit price of consumer's recorded data by data brokers is medium, neither platform adopting privacy protection technology is a lose-lose result for platforms and consumers.

5 - Effective Distribution Strategies for Food Banks: Overcoming Uncertainty in Donations and Food Waste

Xianjia Gao, University of Illinois Urbana-Champaign, Champaign, IL, United States

Food bank, a non-profit humanitarian organization, secures charitable food donations through collaborative partnerships. Food banks are pivotal in mitigating food insecurity by distributing donations to those in need. However, they face several significant challenges. First, food banks depend on uncertain donations from diverse sources such as supermarkets, farms, food manufacturers, and individuals, leading to a highly variable supply. Second, the demand from partner agencies varies, complicating the equitable distribution of food. Moreover, approximately 35% of the distributed food (equating to about 29 million pounds annually) is perishable, making the management of food storage and distribution more complex. To address these challenges, we develop a multi-period dynamic model to help food banks allocate perishable food to agencies, aiming to maximize the value of the food, achieve equitable distribution, and minimize waste. We propose a heuristic algorithm based on fluid approximation with a provable regret upper bound. Furthermore, to tackle the dynamic environment, we further refine the heuristic through reoptimization and prove that the same regret bound can be achieved. Our results demonstrate that the proposed heuristics achieve asymptotic optimality with respect to the size of the food distribution network.

AI Models for Healthcare: Opportunities and Limitations

Invited Session

Health Applications Society

Chair: Kimberly Villalobos Carballo, New York University, New York, NY, United States

1 - A Multimodal Machine Learning Approach for Detection and Prevention of Excessive Treatment of Urinary Tract Infections

Carol Gao, Massachusetts Institute of Technology, Cambridge, MA, United States, Phevos Paschalidis, Dimitris Bertsimas

Urinary Tract Infections (UTIs) account for approximately 3 million visits to the emergency department annually at a cost of approximately \$3.5 billion. Despite being a common infection, challenges persist in making an accurate UTI diagnosis. Urinalysis and urine cultures are often nonspecific and positivity does not necessarily indicate a true UTI. This often leads to systematic overdiagnosis of UTI, which can lead to adverse drug events, unnecessary utilization of antimicrobials, development of organisms with antibiotic resistance, and most importantly, delay targeted interventions and prolong hospital stays due to false positivity. In this paper, we propose a multimodal clinical support tool that will give treating providers the likelihood of pre-testing (urinalysis, urine culture) UTI diagnosis. This tool integrates language data from clinician notes with tabular data extracted from the electronic health records of more than 30,000 patients at Hartford HealthCare. To our knowledge, this is the first application of language data and multimodal AI techniques to UTI prediction. Our model also differs from existing algorithms by making predictions before any tests have been ordered. This addresses overprescription and overtesting at its root cause. Our model achieves a high AUROC of 0.843, surpassing comparative studies. Appropriate choice of thresholds, furthermore, could correspond to a 51% reduction in ordered urinalysis while accurately identifying 90% of UTI positive patients.

2 - Scheduling Surgery Requests from Outdoctors and Indoctors Under Uncertainty

Serhat Gul, TED University, Ankara, Turkey, Arsham Atashi Khoei, Melih Celik

Hospitals increasingly allow surgeons who are not full-time employees (outdoctors) to rent operating rooms (ORs) to generate revenue. However, to have their surgeries scheduled, outdoctors need to compete with the full-time hospital-employed surgeons of the hospital (indoctors) for limited resources. Balancing the needs of both surgeon types while accounting for uncertainty in surgery durations creates a challenging surgery planning problem. To address this problem, we formulate a stochastic mixed-integer programming model to select outdoctor surgery requests and schedule both indocter and selected outdoctor surgeries across ORs and days within a finite planning horizon. Key performance measures include revenue from accepted outdoctor requests, and cost of patient waiting times, and that of expected OR overtime and idle time. To solve the model, we propose a problem-based scenario reduction algorithm based on loss function minimization (LFM). We solve the LFM problem using both a mixed-integer second-order cone programming model and a sub-gradient-based heuristic. As the heuristic provides near-optimal solutions within reasonable time, we adopt it for further experiments using real surgery duration data. We compare our scenario reduction algorithm against three alternatives from the literature. Additionally, we provide insights into the benefits of incorporating outdoctor surgeries into hospital surgery planning and exploring different levels of flexibility in handling these requests. Finally, we perform sensitivity analyses on various model parameters and estimate the value of the stochastic solution.

3 - Algorithmic Bias and Physician Liability

Tinglong Dai, Johns Hopkins University, Baltimore, MD, United States, Shujie Luan, Shubhanshu Singh

With the growing use of artificial intelligence (AI) in clinical decision-making, concerns about bias—manifested as differences in algorithmic accuracy across patient groups—have intensified. In response, the U.S. Centers for Medicare and Medicaid Services (CMS) has introduced a liability rule that penalizes healthcare providers who

rely on biased algorithms that result in erroneous decisions. This paper examines the impact of this anti-bias liability rule on an AI firm's development decision as well as a healthcare provider's decision to use AI. The AI firm develops an algorithm that serves two patient groups, where achieving the same level of accuracy for the disadvantaged group is more costly. The provider then decides whether and how to use AI to make treatment decisions, balancing the reduction in clinical uncertainty against the risk of incurring anti-bias liability. We find the liability rule may induce biased use of AI: The provider may underuse AI overall and disproportionately disregard AI's recommendations for disadvantaged patients. Interestingly, the effect of liability on AI use is non-monotone: as liability increases, the provider is first less likely to use AI for disadvantaged patients, but then more likely to rely on it. Furthermore, mandating equal algorithmic accuracy across patient groups may inadvertently harm all patients, in part because such mandates may lead to overusing AI for disadvantaged patients.

1 - Building Smarter Healthcare Systems with Intelligent Network Design

Shan Liu, University of Washington, Seattle, WA, United States

Many healthcare resource allocation challenges can be framed as geospatial network design problems facing equity-efficiency tradeoffs. This talk will feature two ongoing research using data analytics and optimization models to allocate scarce healthcare resources within a geographic network. In the first research, we minimized the turnaround time for HIV viral load testing by placing point-of-care testing machines in a hub-and-spoke network in Kenya. We designed a user-friendly decision-support tool for Kenyan health administrators, and a queueing-location-allocation model under stochastic demand, formulated as an integer program and incorporating Conditional Value at Risk. In the second research, we focused on assessing disparities in access to high-quality trauma care among sociodemographic groups in Washington state. We developed a set of geospatial and non-geospatial quality metrics and proposed an optimization model that reconfigures hospital functions to improve trauma care quality while addressing fairness concerns. The overarching goal is to ensure timely and location-appropriate access to critical services by leveraging health data and advanced analytics to inform more effective, system-level decision-making.

2 - Towards Multi-Sectoral Decision Analytics for Public Health: Overcoming Modeling Barriers Through IEOR Research and Translation

Chaitra Gopalappa, University of Massachusetts, Amherst, MA, United States

Health outcomes are shaped not only by clinical and behavioral factors but also by intersecting systemic, structural, and social determinants. As a result, there is growing consensus on the need for multi-sectoral, disease-agnostic strategies that integrate health and non-health interventions. However, designing decision-analytic models that can quantify needs and optimize interventions across sectors presents significant technical challenges—ranging from data sparsity and heterogeneity to computational scalability and policy relevance.

In this talk, I will discuss the research trajectory in my lab to address barriers at different levels: (1) large-scale modeling (using single diseases), (2) multi-disease modeling, and (3) multi-sectoral modeling. I will highlight core IEOR research innovation, including an evolving network algorithm using deep learning for developing scalable agent-based network simulations, hybrid simulation framework for joint modeling related diseases and social determinants, copula-informed graphical modeling for social determinants model parametrization, and multi-agent reinforcement learning for optimizing subgroup-specific policies under cross-group mixing. I will also highlight translational efforts in developing decision-analytic models suitable for analyses of national and global policy decisions. Finally, I will provide an overview of ongoing efforts for research, capacity building, and translation in area of multi-sectoral decision analytics.

3 - Innovative Solutions for Healthcare Operations with Scheduling and Analytics

Mehmet Begen, Ivey Business School, Western University, London, ON, Canada

Our research focuses on scheduling and the application of operations research across a variety of industries, with a particular emphasis on healthcare. We address challenges such as optimizing operating room schedules, planning home healthcare operations, designing contracts for pharmaceutical co-development, and evaluating the cost-effectiveness of kidney transplantation. Additionally, we optimize hospital cart planning, assess the efficiency of national cancer treatment centers, forecast inbound transfers of COVID-19 patients, and compare the effectiveness of diverse COVID-19 policies. I am fortunate to collaborate with exceptional colleagues, practitioners, students, and postdoctoral researchers whose dedication propels our work. In this talk, I will highlight several of these projects, share key insights and lessons learned, and outline future research directions.

1 - Do Inspection Delays Lead to Quality Decline? Evidence from U.S. Nursing Homes

Wilson Lin, Santa Clara University, Santa Clara, CA, United States, Lauren Lu, Susan Lu

This research examines the impact of inspection delays on nursing home operations. Using a 8-year longitudinal dataset from 2016-2024, we find that longer interinspection times led to a quality decline in nursing homes, as evidenced by an increase in deficiency citations.

2 - Kidney Allocation Priority and Patient Outcomes: a Regression Discontinuity Analysis

Diwas KC, Emory University, Atlanta, GA, United States, Jiayi Liu

The scarcity of deceased-donor kidneys makes priority rules central to allocation decisions. This study examines how such priority influences patient behavior and transplant outcomes by exploiting an age-based cutoff in U.S. policy. Using a regression discontinuity design, we find that priority increases both the frequency and quality of organ offers, improving graft survival. However, it also reduces living-donor transplants and leads some patients to decline otherwise viable kidneys. These findings point to a tradeoff between expanding access and minimizing unintended selectivity.

3 - Operational Impact of Traveling Nurses on Surgical Teams

M. Eric Johnson, Vanderbilt University, Nashville, TN, United States, Vikram Tiwari, Maksim Yakovlev

This paper examines the operational implications of travel nurse employment in surgical settings. We analyze how variation in nurse workforce composition impacts throughput, coordination, and learning. By examining how the integration of travel nurses affects performance, this study informs the design of staffing models under workforce turnover and surgical complexity.

4 - Promoting Collaborative Care: Relative Performance-Based Payment Models for Hospitals and Post-Acute Care Providers

Hang Ren, George Mason University, Fairfax, VA, United States, Kenan Arifoglu, Tolga Tezcan

Bundled payment models are widely used in healthcare reimbursement but they were primarily designed for conditions managed by a single provider in a centralized manner. Therefore, these models do not account for the complexities of conditions requiring post-acute care (PAC) after hospitalization, resulting in weak incentives for care coordination between hospitals and PAC providers, particularly in decentralized settings. Motivated by the Comprehensive Care for Joint Replacement (CJR) payment model introduced by CMS—which holds hospitals accountable for the cost and quality of the entire episode, including PAC—we examine the effectiveness of existing payment models in decentralized care. Our analysis shows that bundled payment models and the CJR framework, especially without gainsharing agreements, do not fully align provider incentives. To address these shortcomings, we propose a payment model that explicitly links hospital and PAC provider reimbursements. Using a game-theoretical framework, we show that this model results in socially optimal provider actions. Moreover, we establish that similar efficiency gains can be achieved within the CJR framework if hospitals and PAC providers adopt structured gainsharing agreements. Numerical simulations show that implementing this approach could reduce readmission costs by 12%, generating over \$150 million in annual savings for Medicare joint replacement procedures alone.

1 - Optimizing Hpv Intervention Strategies over TIME: a Reinforcement Learning Approach Strategies: a Case Study in Hpv Intervention Planning

Shalome Hanisha Anand Tatapudi, University of South Florida, Tampa, FL, United States, Cody Palmer

The decision-making process in healthcare, especially in the field of infectious diseases, is complex and challenging due to various factors such as disease transmission mechanisms, demographic variables, population behaviors, and available interventions. Disease modeling has proven to be an effective tool for evaluating the implications of policymakers' choices and quantifying the effects of decision-making. However, there is still a need to navigate the tradeoffs between cost-effective and efficient intervention strategies, dynamically. The evolving nature of disease and population further complicates the situation, as strategies that are effective today may become less effective in the future. Therefore, it is essential to examine how present intervention decisions will impact future outcomes and the health of the population at large. In this study, we propose the development of a reinforcement learning model to determine optimal intervention strategies, focusing on a case study of the human papilloma virus (HPV). By developing an intelligible learning model, we can evaluate comprehensive interventions, such as cervical cancer screening and vaccination strategies, at different time intervals and aim to create an optimal policy that spans an extended period. This research will help validate current decisions and provide insights into the long-term impact of our choices on the population's health. Designing effective intervention strategies is crucial for reducing the prevalence of HPV-related diseases and improving overall health outcomes. By leveraging reinforcement learning, which allows systems to learn from feedback and adjust their actions accordingly, we can identify the most efficient and cost-effective approaches to HPV intervention and prevention.

2 - Applying Systems Modeling and Machine Learning Methods to Identify Hidden Figures Underlying Quality Measures

Inas Khayal, Dartmouth College, Lyme, NH, United States

Racial and ethnic disparities persist across many diseases in the U.S., including cancer, diabetes, and heart disease. These disparities are often measured using quality metrics that compare aggregate outcomes between racial groups—typically at a single time point or over fixed intervals, such as the last six months of life. Such a static, aggregated approach may obscure dynamic patterns in care delivery. Understanding these dynamic patterns more realistically elucidates underlying behavior that can be targeted for quality improvement efforts. In this presentation, we apply systems modeling and machine learning to uncover racial inequalities in end-of-life cancer care. First, we replicate traditional quality measures using aggregated metrics. Next, we introduce longitudinal signatures—constructed using the same numerator and denominator but calculated daily over the final six months of life. This method captures temporal variations in care by borrowing from engineering principles to construct richer representations of the time-varying differences in racial group experience. Using machine learning classification, we analyze both aggregate and temporal signatures to identify patterns indicative of racial disparities. Our approach highlights how dynamic modeling can reveal "hidden figures"—previously unrecognized inequalities—in care trajectories that are masked by static measures. This work demonstrates the value of integrating systems engineering and machine learning to advance equity-focused healthcare analytics and inform decision-making.

3 - An Order-Based Bayesian Network Approach for Analyzing Diagnostic Delays and Type 2 Diabetes-Related Health Outcomes in Primary Care

Yukti Kathuria, University of Massachusetts Amherst, Amherst, MA, United States, Muge Capan, Kristen Miller, William Gallagher, Elizabeth Selden

Chronic disease diagnosis and management in primary care relies on regular and timely monitoring. Additionally, the risk for diagnostic delay is not uniform across all patient subpopulations. While previous research has explored individual risk factors or used traditional regression models to assess Type 2 Diabetes (T2D) outcomes, few studies have captured diagnostic delay and the temporal and probabilistic dependencies among variables. Even fewer have done so using a structured framework that reflects the clinical sequence of events from demographics to diagnosis to post-diagnosis care. Our study addresses this gap by applying an order-based Bayesian Network (BN) to analyze how demographic factors and diagnostic delay surrogates influence T2D related health outcomes in primary care.

Using de-identified Electronic Health Record data of adult patients (N=2288) in two primary care practices over a 7-year study period, we constructed a three-layered BN informed by literature and clinician input. The model incorporated imputed, distributionally fitted data to reflect uncertainty and patient heterogeneity. Higher diagnostic lab levels were consistently associated with increased glycemic variability, while the effect of care continuity factors on outcomes varied by delay status, highlighting distinct pathways from diagnosis to post-diagnosis across patient subpopulations.

By modeling the care pathway as an ordered, probabilistic system, our approach offers a nuanced understanding of T2D progression. This enables dynamic risk assessment, helping identify subpopulations at higher risk of poor outcomes. These insights can support personalized and timely interventions to improve diabetes care across diverse patient populations.

4 - Optimizing Multidisciplinary Care: Online vs. Offline Scheduling Approaches

Sindhoora Prakash, University of Massachusetts Amherst, Amherst, MA, United States, Hari Balasubramanian, Chaitra Gopalappa

Complex care programs aim to reduce long-term healthcare expenses and promote patient well-being and self-efficacy through coordinated, lower-cost interventions delivered by multidisciplinary teams comprising both healthcare and social service professionals. These programs face significant challenges in workforce planning and resource allocation due to the non-stationary nature of both intervention arrival rates and service rates. In this talk, we examine three distinct approaches to scheduling interventions within such programs. First, we present a Mixed-Integer Linear Programming model with perfect information, serving as an idealized performance benchmark. Second, we evaluate a simple First-Come, First-Served heuristic that offers a straightforward, easily implementable baseline. Finally, we introduce an online Reinforcement Learning-based scheduling algorithm that makes adaptive, data-driven decisions in real time. We assess the efficiency and effectiveness of these methods by analyzing the distribution of daily workload across staff members and the average delay experienced by patients, offering insights into the trade-offs between optimality, responsiveness, and practical implementation in dynamic care environments.

5 - Unsupervised Learning Approaches to Detect Patterns in the Co-Occurrence of Diseases: Evidence from Medical Expenditure Panel Survey (MEPS)

Ali Jafari, University of Massachusetts Amherst, Amherst, MA, United States, Hari Balasubramanian

Understanding the relationships between diseases is one of the crucial aspects in healthcare and clinical practice. While certain associations between diseases, such as diabetes and hypertension (high blood pressure), are well established, others remain less obvious, and may remain undetected. In this study we use the Medical Expenditure Panel Survey (MEPS 2016 - 2019) to study associations between diseases. The MEPS provides comprehensive patient information, including specific

medical conditions indicated by their corresponding International Classification of Diseases, Tenth Revision (ICD-10) codes. We structured a dataset from the MEPS records, facilitating access to individual disease profiles. Subsequently, we applied the Apriori algorithm to identify various disease combinations and association rules. Moreover, we implemented a novel unsupervised learning algorithm to perform clustering, offering deeper insights into the interrelations among diverse disease categories. Using these methodologies, we aim to enhance our understanding of disease relationships, potentially contributing to more effective healthcare strategies and interventions.

6 - Decentralized Training Decentralized Execution Using a Shared Network (DTDE-SN) a New Reinforcement Learning Approach for Epidemic Modeling

Sonza Singh, University of Massachusetts, Amherst, Amherst, MA, United States, Chaitra Gopalappa

Multi-agent reinforcement learning (MARL) methods are suitable tools for modeling highly dynamic decision analyses such as intervention analyses in epidemic outbreaks across multiple jurisdictions. MARL models allow us to consider jurisdictional mixing interactions in the decision-making policies, as they evaluate decisions specific to each jurisdiction while considering the interactions between all jurisdictions. In multi-agent reinforcement learning, there are three commonly used training and execution paradigms. Centralized training with centralized execution (CTCE) converts a multi-agent problem into a single-agent problem by considering the joint state/action space of all agents as that of a single virtual agent. Centralized training with decentralized execution (CTDE) trains agents using centralized information but executes their actions independently based on their local observations. Decentralized training with decentralized execution (DTDE) trains agents independently to optimize team rewards, and each agent regards other agents as a part of the environment. We propose a new training and execution approach, where a single deep learning model (which considers the interactions between agents) is trained for all agents but each agent makes its own independent decisions. The standard DTDE approach trains a separate network for each agent. This approach is computationally complex, and this complexity grows with the number of agents. The new method, which we call decentralized training with decentralized execution using a shared network (DTDE-SN) models interactions between agents while reducing computational complexity. We used a HIV epidemic compartmental simulation model composed of multiple jurisdictions as a case study to demonstrate that the DTDE-SN method can identify optimal intervention decisions.

1 - Joint Pricing, Salvaging, and Inventory Replenishment Through Store Assignment

Deniz Akturk, Washington University in St. Louis, St. Louis, MO, United States

We consider a joint problem of pricing, replenishment, and salvaging across multiple stores connected to multiple warehouses. Given an initial allocation of units across warehouses and stores, the firm must determine replenishment quantities from warehouses to stores and replenishment quantities between warehouses. Additionally, the firm dynamically determines the prices charged at each store and the number of units to be sold through secondary channels at each store. Formulated as a discrete-time, non-stationary Markov Decision Process, the problem faces significant computational challenges due to the curse of dimensionality and non-linear replenishment costs. We show that this problem can be equivalently represented as an assignment problem, where stores are assigned to specific inventory and price combinations. Through this framework, we can express the problem using linear cost functions without any loss of optimality. This equivalent representation also enables a discrete mean-field approximation, which extends the standard mean-field formulation by providing discrete, feasible decisions. We prove that the discrete mean-field policy provides a sub-linear optimality gap in the number of stores and warehouses. Moreover, we also prove that the mean-field model provides a lower bound to the optimal cost, which numerical experiments indicate is attained for larger networks. The generality of our assignment-based reformulation allows for its application to broader joint inventory and pricing problems with non-linear costs. Through numerical experiments, we show that the discrete mean-field model performs near-optimally across various scenarios, including settings with a limited number of stores and settings where all stores have varying properties.

2 - Dynamic Matching Under Unbalanced Impatience

David Chen, The Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Zhiyuan Chen, Ming Hu, Yun Zhou

We consider an infinite-horizon dynamic matching problem in two-sided markets, where agents on one side, say, supply agents, are long-lived, and agents on the other, say, demand agents, are impatient. Agents of high and low quality arrive at the platform sequentially, and the matching reward has a supermodular structure. Our analysis reveals that in a centralized setting, prioritizing high-quality supply for high-quality demand maximizes matching rewards; conversely, low-quality demand should be paired with low-quality supply. In decentralized scenarios, we identify a welfare-maximizing equilibrium, in which high-quality demand is matched with high-quality supply first, followed by low-quality supply. Low-quality demand is matched with high-quality supply only when the number of high-quality agents is large and with low-quality supply only when the number of high-quality agents is small and the number of low-quality agents is large. Moreover, the decentralized matching process can be coordinated to achieve the centralized one by adjusting the reward allocation. These findings suggest that matching platforms should adopt differentiated matching strategies based on agent quality, balancing short-term satisfaction with long-term efficiency. Finally, we show that allowing agents to wait may or may not enhance social welfare in a decentralized setting. If the majority of rewards favor the patient supply side, waiting can be beneficial; however, if impatient demand agents receive most of the rewards, waiting could lead to diminished social welfare. This further highlights the importance of reward allocation in coordinating matching processes and managing queues effectively.

3 - Optimal Policies for Dynamic Pricing and Inventory Control with Nonparametric Censored Demands

Boxiao Chen, University of Illinois Chicago, Chicago, IL, United States, Yining Wang, Yuan Zhou

We study the classic model of joint pricing and inventory control with lost sales. The firm does not know the demand distribution a priori and needs to learn it from historical censored demand data. We develop nonparametric online learning algorithms that converge to the clairvoyant optimal policy at the fastest possible speed.

4 - An Integrated Approach to Airline Flight Network Expansion and Fleet Assignment Decisions

M. Selim Akturk, Bilkent University, Ankara, Turkey, Özge Şafak Aydın, Deniz Akturk, Alper Atamturk

The ability to match fleet capacity with growing passenger demand is crucial for airline profitability. This work develops a mathematical model that enables airlines to assess the incremental impact of each new flight request and to determine the optimal number of leased aircraft, while simultaneously building a schedule with new market routes, allowing a reliable estimate of operational costs and revenue. Given that the costs of fuel consumption and carbon emissions represent the largest components of operational expenses, the model integrates strategic network expansion decisions with operational aircraft assignment considerations. Consequently, we account for not only the seat capacity of the aircraft alternatives but also the fuel efficiency and environmental impact of the aircraft for the fleet assignment problem. Finally, by generating a new flight schedule in the proposed integrated approach, we could analyze the impact of time-dependent ticket prices for new flight requests as a function of their flight departure times.

5 - Inventory Systems with Record Inaccuracy: Transaction Errors vs. Unobservable Loss

Naveed Chehrizi, Washington University in St Louis, Saint Louis, MO, United States

We present a continuous-time Bayesian model for managing inventory in a retail setting when inventory records are inaccurate. In our formulation, the inventory level and its record have separate dynamics. The former is driven by the demand and unobservable loss process while the latter is driven by the demand and transaction error process. We analytically characterize the dynamics of the retailer's belief on the shelf inventory level and prove that the optimal restocking policy is a threshold policy. In contrast to prior conjectures, we show that transaction errors play a prominent role in increasing the uncertainty in the shelf inventory distribution. In addition to this

confounding effect, the presence of transaction errors breaks the retailer's ability to calculate this distribution by tracking a small set of sufficient statistics: it remains a function of the entire observed history. Hence, computing the optimal restocking policy, even though we obtain its exact analytical form, remains numerically intractable. We tackle this "curse of dimensionality" by dynamically adjusting the problem's underlying information filtration. This effectively projects the dynamics of the inventory level onto a manifold that is adaptively adjusting to the information revealed by the inventory record process. Adding this extra layer of adaptation, implemented by *dynamic filtration*, enables us to reduce the dimensionality of the problem by an arbitrary degree. We show that the resulting implementable policy, which is optimal for the chosen dynamic filtration, also exhibits significant robustness to model misspecification.

1 - Minimum Cost Nowhere-Zero Flows and Cut-Balanced Orientations

Siyue Liu, Carnegie Mellon University, Pittsburgh, PA, United States, Karthekeyan Chandrasekaran, R. Ravi

Flows and colorings are disparate concepts in graph algorithms---the former is tractable while the latter is intractable. Tutte introduced the concept of nowhere-zero flows to unify these two concepts. Jaeger showed that nowhere-zero flows are equivalent to cut-balanced orientations. Motivated by connections between nowhere-zero flows, cut-balanced orientations, Nash-Williams' well-balanced orientations, and postman problems, we study optimization versions of nowhere-zero flows and cut-balanced orientations. Given a bidirected graph with asymmetric costs on two orientations of each edge, we study the min cost nowhere-zero k -flow problem and min cost k -cut-balanced orientation problem. We show that both problems are NP-hard to approximate within any finite factor. Given the strong inapproximability result, we design bicriteria approximations for both problems. For the case of symmetric costs (where the costs of both orientations are the same for every edge), we show that the nowhere-zero k -flow problem remains NP-hard and admits a 3-approximation.

2 - Capacitated Incomplete Hub Network Design Problem with Link Congestion

Mahsa Sheikhihafshejani, Oregon State University, Corvallis, OR, United States, Hector Vergara

This work addresses an incomplete hub network design problem with capacity constraints and congestion cost for inter-hub links. We formulate the problem to identify hub locations, design the inter-hub network, and route demand flows through the network. The objective is to minimize the total cost, including fixed setup costs for hubs and links, transportation costs, and nonlinear congestion costs on the links. The problem is formulated as a mixed-integer program, where link congestion costs are approximated using a piecewise linear function. A heuristic-based method is proposed to solve the problem efficiently. The heuristic method begins by ranking nodes and links based on demands between nodes for inclusion in the network and iteratively designing the hub network based on this ranking. The solution is further improved using a variable neighborhood search method to find quality solutions. Computational experiments on two well-known benchmark datasets demonstrate that the proposed solution method can obtain high-quality solutions within a reasonable computational time. Finally, we conduct a sensitivity analysis with different parameter settings to evaluate the hub network and the impact of link congestion.

3 - Connected Dominating Sets Interdiction Problem

Haonan Zhong, Yunnan University of Finance and Economics, Kunming, China, People's Republic of, Foad Pajouh, Oleg Prokopyev

This study introduces and investigates the problem of interdicting connected dominating sets in a network via blocking edges. Given a network with weights assigned to its vertices and blocking costs associated with its edges, the decision maker aims to block a minimum cost subset of edges to increase the minimum weight of any connected dominating set in the remaining network above some desired threshold. This problem has important applications in effectively blocking the distribution of information, products and funds within adversarial social, communication, and supply networks. We explore the computational complexity of this problem and identify the collection of its feasible solutions. We then formulate this problem as a binary integer program, introduce three classes of facet-inducing inequalities for the convex hull of its feasible solutions, and develop a lazy branch-and-cut method for solving it. We also propose a combinatorial branch-and-bound algorithm which utilizes purely combinatorial bounds to implicitly enumerate the search space. The performance of our proposed methods are then compared on randomly-generated and real-life instances.

4 - Fair Network Design Problem: An Application to EV Charging Station Capacity Expansion

Nagisa Sugishita, HEC Montréal, Montréal, QC, Canada, Margarida Carvalho, Okan Arslan, Yossiri Adulyasak, Amira Dems

This study addresses the bilevel network design problem (NDP) with congestion. The upper-level decision-maker (a network designer) selects a set of arcs to add to an existing transportation network, while the lower-level decision-makers (drivers) respond by choosing routes that minimize their individual travel times, resulting in user equilibrium. In this work, we propose two novel single-level reformulations: one based on strong duality and the other based on the value function of the lower-level problem. Unlike existing approaches in the literature, which are specialized for optimizing the total travel time of all drivers, our approach is flexible and can optimize other metrics related to individual travel times or fairness. We discuss the differences between the two reformulations, as well as their computational performance on academic test instances of the NDP. We then apply our methods to the EV charging station capacity expansion problem. We define a metric, the cost of sustainability, to measure the service quality experienced by individual EV drivers, and optimize the charging station locations to improve this metric. We present the results of experiments using the road network in Quebec, including public fast EV charging stations.

5 - Multi-Tier Network Design Optimization in Physical Internet (Pi) Based Hyperconnected Urban Logistics

Praveen Muthukrishnan, Georgia Institute of Technology, Atlanta, GA, United States, Xiaoyue Liu, Benoit Montreuil

To meet the increasing demand for faster, more reliable, and sustainable logistics services in urban areas, the Physical Internet (PI) framework proposes a transformative approach to urban freight distribution. It envisions an open, hyperconnected logistics network underpinned by a hierarchical spatial structure. In this system, an urban region is discretized into unit zones -each representing clusters of customer locations - which are aggregated into local cells, and further into larger urban areas. Correspondingly, the logistics network is organized into three interconnected tiers of hubs: Access hubs (AH) serving flows between unit zones, Local hubs (LH) managing flows between local cells, and Gateway hubs (GH) coordinating flows between urban areas. This structure facilitates the consolidation of parcel flows, promotes systemic efficiency and sustainability.

This paper contributes to the development of such a system by introducing an optimization framework for the design and placement of hubs across all tiers of the urban logistics network, informed by hub capabilities and service requirements. The framework explicitly models inter-hub flows, supports robust and modular capacity planning, and incorporates real estate data (e.g., from CoStar) to identify opportunities for repurposing existing infrastructure and buildings. Further, a case study focused on Metro Atlanta demonstrates the feasibility and effectiveness of the proposed approach, highlighting its potential to support data-driven and scalable decisions for future urban logistics systems across wider geographical regions.

6 - Large-Scale Network Optimization for Haul Ramp and Road Design in Open-Pit Mining

Bingshen Lu, Colorado School of Mines, Golden, CO, United States, Felix Ayaburi, Alexandra Newman, Dinesh Mehta

Haul road optimization in open-pit mining aims to reduce fuel consumption and operational costs by improving ramp and haul road design for large haul trucks. Traditional methods rely on heuristics and often overlook the impact of terrain, slope, and truck constraints on efficiency. We model the mine surface as a 3D graph which nodes are connected based on distance and slope thresholds. Using Python and NetworkX, we design ramps using graph theoretic path-finding algorithms. Paths minimize fuel consumption under "reasonable" characteristics, e.g., distance, gradient, turn radius. This allows us to generate realistic, fuel-efficient haul routes for Komatsu 930Es and Hitachi EH5000ACs. We read data from AutoCAD mine design files to ascertain coordinates and terrain type based on data at 3 million nodes. Outputs yield interactive plots of paths with multiple origin-destination pairs; objective function weightings generate paths with different characteristics. Current results demonstrate optimized surface paths that reduce fuel usage. Future work will extend to subsurface planning, evaluating the trade-offs between material removal and long-term haulage efficiency.

1 - Encoding Spatiotemporal Patterns for Counter-Trafficking Intelligence

Nickolas Freeman, The University of Alabama, Tuscaloosa, AL, United States, Greg Bott, roya shomali

Adult service websites (ASWs) host advertisements for commercial sex services. Several sources suggest that some portion of advertisements can be linked to victims of human trafficking. Law enforcement, non-profit organizations, and researchers have focused on transforming ASW data into actionable intelligence for counter-trafficking interventions. However, existing analytical approaches largely rely on analyzing advertisement text, overlooking geographical and temporal movement patterns. This research examines methods to represent and analyze the spatiotemporal patterns in ASW data. We develop techniques to transform sequences of geographical locations and timestamps into vector representations that enable similarity assessment between different movement profiles. These vector-based approaches allow analysts to identify common trafficking corridors, link seemingly unrelated advertisements, and detect anomalous movement patterns. We evaluate several methods for constructing representations, compare their performance using a large multi-site dataset, and demonstrate how incorporating spatiotemporal analysis can enhance counter-trafficking efforts.

2 - Multi-Objective Humanitarian Logistics in Flood-Affected Urban Areas: Coordinated Truck-Drone Delivery with Fairness and Disinformation Considerations

Ramin Talebi Khameneh, Stevens Institute of Technology, Hoboken, NJ, United States, Jose Ramirez-Marquez, Nafiseh Ghorbani-Renani

Humanitarian logistics in post-disaster urban environments must address complex challenges, balancing rapid response with equitable aid distribution. This study addresses a multi-objective optimization problem for humanitarian aid delivery using coordinated trucks and drones, with the dual goals of minimizing total travel distance and maximizing fairness among aid recipients. We develop a mathematical model where each drone operates in tandem with a truck from a shared depot, navigating urban constraints such as damaged infrastructure and limited access. To solve this NP-hard problem, we employ both an Exact solver and the NSGA-II metaheuristic algorithm, enabling a comparative evaluation of performance and solution quality.

We validate our approach through two case studies: (1) the Hoboken flood scenario, examining variations in recipient population sizes; and (2) the West Kentucky flood, where we introduce the novel dimension of weaponized disinformation, modeled as false service requests. In this second case, we incorporate Social Vulnerability Index (SVI) data to probabilistically determine whether to serve potentially fake requests, with higher-SVI nodes receiving the benefit of the doubt to enhance social equity.

The results demonstrate that while Exact methods are suitable for small-scale instances, NSGA-II offers scalable, high-quality solutions across both objectives. These findings contribute to the development of resilient, data-driven disaster response systems capable of addressing both logistical efficiency and ethical distribution concerns under real-world uncertainties.

3 - Perception-Enhanced Vulnerability Analysis: a Human-Centric Vulnerability Metric Framework Using Multimodal Social Intelligence for Disaster Response

Amirhossein Dezhbor, Stevens Institute of Technology, Hoboken, NJ, United States, Rosario Contreras Galvan, Jose Ramirez-Marquez

Traditional flood risk assessment models rely on static vulnerability indices that fail to capture real-time community conditions during disaster events. This research develops a dynamic risk assessment framework that integrates social perception through multimodal social media analysis to enhance flood vulnerability metrics for humanitarian operations. The methodology builds upon conventional risk assessment by introducing a social perception modifier derived from real-time community data. System vulnerability encompasses population vulnerability based on age demographics and disability status, infrastructure vulnerability considering critical facility density and building age, and emergency response capacity. Flood intensity is modeled using physics-based hydrological simulation incorporating precipitation,

topography, and drainage systems. The key innovation lies in the social perception component, extracted through three-layer analysis: content analysis of text, images, and videos using natural language processing and computer vision; communication flow analysis measuring information volume and propagation patterns; and temporal alignment analysis across warning, impact, and recovery phases. The enhanced risk assessment integrates social perception as a dynamic modifier reflecting community-reported severity and spatial impact distribution. This approach transforms static vulnerability assessment into a responsive system incorporating local knowledge and situational awareness from affected populations. Implementation in Guadalajara, Mexico demonstrates the framework's effectiveness in capturing community-perceived risk variations that traditional metrics miss. The methodology addresses critical gaps in humanitarian operations by enabling real-time risk recalibration based on population feedback, supporting targeted emergency response allocation. The framework provides a replicable methodology for integrating human-centered data into quantitative risk models, advancing disaster management theory and humanitarian operations practice.

4 - Bridging Artificial Intelligence and Large Language Models for Poverty Research: Fine-Tuning Llama 3.2 1B for Multidimensional Poverty Prediction

Zahra Zarei Ardestani, Worcester Polytechnic Institute, Worcester, MA, United States, Aaron Belikoff, Raha Moraffah, Robert Krueger

The integration of artificial intelligence (AI) and large language models (LLMs) in poverty research remains unexplored. While machine learning and AI have been applied in various domains, their use in poverty analysis is limited, and no prior studies have leveraged state-of-the-art AI for this purpose. In this research, we introduce a novel approach that incorporates LLMs into poverty research by fine-tuning LLaMA to predict the multidimensional poverty index (MPI).

Traditionally, calculating MPI requires converting survey data into a structured format suitable for statistical analysis, followed by complex coding and computations. This process is labor-intensive, time-consuming, and demands expertise in statistics—resources that are often scarce in low-income countries. The financial and logistical challenges associated with these traditional methods frequently lead to delays or even the suspension of poverty analysis, hindering effective policy interventions.

To address these challenges, we propose a method that eliminates the computational overhead associated with survey analysis. By fine-tuning LLaMA 3.2 1B, we enable the model to directly interpret survey responses in text format and generate poverty index predictions without the need for numerical conversions or extensive calculations. This breakthrough significantly streamlines the analysis process, making poverty research more accessible and feasible for resource-constrained regions.

Our supervised fine-tuning approach resulted in 98% accuracy in predicting poverty indices, demonstrating that the model effectively understands the concept of poverty. This research highlights the transformative potential of AI and LLMs in humanitarian applications, paving the way for more efficient poverty assessment, and helping policy makers in addressing poverty and allocating resources.

5 - Optimizing Criminal Investigation Resource Allocation via Predict-Then-Optimize Framework

Vasuki Garg, North Carolina State University, Raleigh, NC, United States, Osman Ozaltin, Maria Mayorga, Sherrie Bosisto

Thousands of Illicit Massage Businesses (IMBs) are estimated to be operating in the United States by disguising themselves as legitimate establishments while exploiting trafficked workers, thereby harming both the victims and the massage industry. The increasing digital presence of these illicit businesses presents an opportunity for detection, a crucial task for law enforcement and social service agencies aiming to disrupt their operations. However, investigative agencies have limited resources and are unable to investigate every business, making it essential to allocate resources optimally. While state-of-the-art machine learning models can predict the likelihood of a business being illicit and help prioritize investigations, these predictions are often decoupled from downstream resource allocation decisions, such as investigation time and budget. Our research bridges this gap by leveraging business reviews from Yelp.com, enriched with data from RubMaps.ch, U.S. Census records, GIS data, and licensing information. We integrate predictive analytics with prescriptive decision-making through a predict-then-optimize approach, enabling resource-aware investigation prioritization.

MSOM: Supply Chain

Chair: Lifei Sheng, University of Houston Clear Lake, Houston, TX, United States

1 - Large Language Models in Hiring Evaluation: Bias Towards Social Class Background

Yao Yao, University of Houston, Houston, TX, United States, Meng Li, Lai Wei

Large Language Models (LLMs), such as ChatGPT, with their advanced reasoning capabilities, offer significant potential as decision-support tools in hiring evaluations. LLMs have been found to excel at content generation, but their fairness and reliability as evaluators remain unknown. Prior research has documented that human recruiters exhibit bias towards candidates' social class backgrounds, but it is unclear whether, why, and when LLMs replicate or mitigate such biases. In this study, we conduct controlled experiments systematically manipulating social class signals. Both LLMs and human evaluators are tasked with assessing candidates from various social class backgrounds. Our experimental approach aims to identify the stages and types of signals that contribute to evaluative bias.

2 - Selling and Renting Mechatronics

Xianfeng Meng, Smith School of Business, Queen's University, Kingston, ON, Canada, Guang Li, Anton Ovchinnikov

Motivated by the rise of mechatronics (a fusion of digital control systems and physical products, such as automobiles where software can unlock advanced functionalities), we examine how mechatronic firms should market their products. Employing a Stackelberg game model, we investigate two strategies: selling both high- and low-end products or offering just the low-end product with an option for consumers to rent the high-end functionality. Our analysis begins by characterizing consumer behavior, followed by deriving the optimal selling and renting strategies. We identify a critical physical-vs-digital threshold: below it, selling is more advantageous, while above it, renting prevails. Our findings reveal that the optimal strategies of mechatronic firms may resemble those of either traditional physical goods firms or digital goods firms. However, merely possessing mechatronic capabilities alone does not guarantee the successful implementation of digital-like strategies. We also assess the impact on consumer welfare and discover that below the physical-vs-digital threshold, both the firm and consumers benefit from the selling strategy, resulting in a win-win situation. However, above the threshold, a misalignment may emerge between the firm's strategy and consumer welfare. Curiously, this misalignment typically occurs when the firm offers its low-end product for free while charging a high price for renting the high-end functionality, capturing almost the entire consumer surplus. This research advances the literature on business models traditionally available to physical and digital goods firms separately, explaining how mechatronic firms can merge strategies from the physical and digital realms, leveraging digital technologies to enhance product offerings.

3 - Rethinking Incentive Design in Response to AI Adoption

BO PANG, National University of Singapore, Singapore, Singapore, YUTING ZHU

The widespread adoption of AI across industries is fundamentally reshaping workplace dynamics and raises critical questions about the design of incentive schemes. This paper addresses a central question: how does the integration of AI systems influence the structure of organizational incentives? To explore this, we develop a game-theoretic model within a contract-theoretic framework that captures the interaction between AI systems and human agents. Our model examines how the presence of AI affects both individual incentives to exert effort and the composition of the workforce in terms of skill—capturing what we define as the incentive effect and the selection effect, respectively. By characterizing distinct patterns of human-AI interaction, the model uncovers the underlying mechanisms driving each effect. Our findings offer new insights into how the interplay between AI and human agents shapes optimal incentive design across different organizational contexts.

4 - Data-Driven Joint Flexibility and Capacity Planning Under Service Level Considerations

Min Liu, Tsinghua University, Beijing, China, People's Republic of, Shixin Wang, Yong Liang

We study a joint flexibility and capacity planning problem in a resource allocation system with multiple resources and demands. The decision-maker aims to ensure a high probability of meeting demands with varying service-level requirements. We propose a two-stage distributionally robust chance-constrained framework to model the problem, addressing the challenge of demand data scarcity, and present a solution approach based on a reformulation of the problem as a mixed-integer linear programming (MILP) problem. Leveraging our model and analysis, we investigate the performance of the widely celebrated long-chain structure under service-level constraints, where resource capacities are treated as decision variables and may vary across resources. Our findings complement the existing literature, which predominantly examines the performance of chaining structures under the maximum flow objective with fixed identical resources. Specifically, we identify conditions under which the long-chain structure is optimal and those under which it is suboptimal. Our findings suggest that low demand volatility and restriction to identical capacities are strong indicators of the long-chain structure being optimal. However, allowing for a high tolerance of unmet service-level requirements or introducing significant demand volatility can make the long-chain structure suboptimal even under identical capacities. Additionally, allowing for deviations from identical capacities typically leads to the suboptimality of the long-chain structure. Interestingly, the long-chain structure can maintain its optimality in situations with low demand volatility, even without the restriction of identical capacities.

5 - Managing Road Safety in Gig Work: Can Recommender Systems Save Lives?

Varun Karamshetty, National University of Singapore, Singapore, Singapore, Nakyung Kyung

Food-delivery drivers make frequent, complex decisions about which tasks to accept, often while on the move. This cognitive load can lead to distraction and increase the risk of accidents. Recommender systems, which streamline task selection by offering optimized suggestions, may help mitigate this risk. We investigate whether adopting a task recommender system reduces accident rates among food delivery drivers. We also examine what happens after adoption—specifically, whether drivers maintain adherence to recommendations after experiencing road accidents. Traumatic events such as accidents can prompt individuals to reclaim a sense of personal agency. Because recommender systems may be perceived as undermining that agency, we explore whether accidents lead to reduced system adherence. We partnered with South Korea's largest food-delivery platform and analyzed behavioral and safety data from 8,883 drivers, some of whom adopted a task recommender system. Using a quasi-experimental design and a Difference-in-Differences framework combined with Propensity Score Matching, we compared outcomes between adopters (treatment) and matched non-adopters (control). Drivers who adopted the system experienced an 85% reduction in at-fault accidents and a 65% reduction in total accidents. They also saw a 9.52% increase in earnings and a 0.84 percentage point increase in on-time deliveries. However, within the adopters, adherence to recommendations declined by 2.9% following an accident. Our study provides the first empirical evidence on how adopting a task recommender system impacts the physical safety of gig workers, and how road accidents impact the post-adoption recommendation adherence.

Mostly Queueing: Abandonment, Control, Pricing, and Signaling in Stochastic Systems

Invited Session

MSOM: Service Operations

Chair: Philipp Afèche, University of Toronto, Rotman School of Management, Toronto, ON, Canada

1 - Quantitative Gaussian Approximation for Queues with Abandonment via Wasserstein Bounds

Zedong Wang, ISyE Georgia Tech, Atlanta, GA, United States, Siva Theja Maguluri

The steady-state distribution of $M/M/1+M$ queue—a single-server queue with exponential rate of abandonment—has been shown to converge to Gaussian in heavily overloaded regime as the abandonment rate goes to zero. However, for pre-limit abandonment rates, the distributional behavior remains less understood. In this work, we consider a new tractable framework, well suited for Birth Death Process, to quantitatively characterize the steady-state queue length by establishing upper bounds on the **Wasserstein- p** distance between the normalized queue length and a standard normal distribution. This framework not only recovers classical Gaussian convergence but also yields Berry–Esseen-type convergence rate. Furthermore, the tightness of our bound captures subexponential and Bernstein-type tail behavior, offering a better understanding of the pre-limit queue behavior in heavily overloaded regimes.

2 - An Online Learning Approach to Pricing in Double-Sided Queues

Zicheng Wang, The Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Saif Benjaafar, Xinyun Chen, Xiaotang Yang

We study pricing in a double-sided queue with impatient agents (customers on one side and servers on the other). The service provider seeks to set prices to charge customers and wages to pay servers to maximize cumulative expected profit. We propose an online learning framework for settings where the demand and supply functions, as well as the abandonment rates, are unknown. The algorithm employs a user-level randomization scheme to estimate the gradient of the objective function. We validate the effectiveness of the algorithm through both theoretical analysis and simulation experiments.

3 - An Equilibrium Solver for A Dynamic Queueing Game

Denise Cerna, University of California, Berkeley, Berkeley, CA, United States, Chiwei Yan, Hongyao Ma

Consider the allocation of deceased donor organs to patients in transplant wait lists, or the dispatch of ridesharing trips to drivers lining up at airports. In these dynamic queueing games, heterogeneity in items and agents' ability to decline offers often induce substantial cherrypicking, resulting in high rates of unfulfilled trips and discarded organs. Existing research typically focuses on simple, easy-to-analyze dispatch rules, sometimes making fluid assumptions for tractability. In this work, we introduce an analytical, best-response-based solver for general dispatch rules with completely closed-form updates. It computes agents' equilibrium strategy regarding whether to accept their received items and whether to join the queue or renege given the evolving queue length and their queue positions. Assuming homogeneous agents and stationary Poisson arrivals, we first provide a necessary condition for a Markov Perfect Equilibrium. We also prove that this equilibrium exists and that our solver always converges for dispatch rules where items are offered monotonically down the queue, and dispatch probabilities over queue positions are independent of queue length. Via extensive simulations, we show that the solver recovers known results for policies that can be analyzed theoretically, and provides insights beyond what had been gleaned from previous analysis. Moreover, the solver converges even for policies without theoretical guarantees, allowing market designers to gain insight into more complex policies better suited for practice.

4 - Dynamic Control of a Make-to-Order Manufacturing System Under Throughput Time Constraints: An Effective Computational Method in the High-Dimensional Case

Chun Li, Booth School of Business, The University of Chicago, Chicago, IL, United States, Baris Ata, NIAN SI

We consider dynamic control of a make-to-order production system that serves price- and delay-sensitive customers. The production system is modeled as a multiclass queueing network where the customers' delay sensitivity is modeled via throughput-time constraints. To maximize her profit while meeting these throughput time constraints, the system manager uses three different types of control: i) dynamic pricing decisions; ii) dynamic order-of-service (sequencing) decisions; and iii) outsourcing decisions upon arrival of new orders. We approximate this problem by a multi-dimensional Brownian control problem in heavy traffic, and develop a neural network-based computational method tailored for high-dimensional problems. By interpreting the solution in the context of the original model, we propose an integrated dynamic pricing, outsourcing, and scheduling policy. The effectiveness of this policy is demonstrated through a simulation study.

5 - Decentralized Signaling Mechanisms

Krishnamurthy Iyer, University of Minnesota, Minneapolis, MN, United States, Niloufar Mirzavand Boroujeni, William Cooper

We study a system composed of multiple distinct service locations that aims to convince customers to join the system by providing information to customers. We cast the system's information design problem in the framework of Bayesian persuasion and describe centralized and decentralized signaling. We provide efficient methods for computing the system's optimal centralized and decentralized signaling mechanisms and derive a performance guarantee for decentralized signaling when the locations' states are independent. This tight guarantee states that the probability that a customer joins under optimal decentralized signaling is bounded below by the product of a

strictly positive constant and the probability that a customer joins under optimal centralized signaling. We also consider more-general objectives for the system and establish that the same guarantee continues to hold. We extend our analysis to systems where the locations' states are correlated, and again derive a performance guarantee for decentralized signaling. For the correlated setting, we prove that the guarantee's asymptotic dependence upon the number of locations cannot be substantially improved. A comparison of our guarantees for independent locations and for correlated locations reveals the influence of dependence on the performance of decentralized signaling.

Data-Driven Operations

Invited Session

Manufacturing and Service Operations Management (MSOM)

Chair: Lennart Baardman, University of Michigan, Ann Arbor, MI, United States

1 - Assortment and Fulfillment Optimization in Online Grocery Retail

Hyun-Soo Ahn, University of Michigan, Ann Arbor, MI, United States, Lennart Baardman, Renjun Hu

Despite the rapid growth of online grocery retail in recent years, most supermarkets have not turned this growth into a profitable business model. One of the key reasons is the excessively high picking and delivery cost in an industry with low profit margins. Technological innovation, in the form of the Micro Fulfillment Center (MFC), has great potential to reduce costs by improving the efficiency in picking operations. The MFC is a small local warehouse, often attached to a brick-and-mortar store or regular fulfillment center, which very efficiently fulfills a subset of items that are available in the assortment of the online store. For a grocery retailer with an online store and an MFC, it is important to decide which items are offered in the assortment of the online store and which items are fulfilled from the MFC. This is especially important in online grocery retail where cart abandonment is ubiquitous. If customers cannot find the items they are looking for, they can abandon their shopping cart and move to another online grocery retailer. In this work, we formulate the assortment and fulfillment problem for an online grocery retailer with an MFC whose customers exhibit cart abandonment behavior. We show that this problem is difficult to solve, and hence, we develop an algorithm to quickly compute near-optimal decisions at large scale. Our algorithm is shown to be a good approximation with theoretical results and computational experiments.

2 - How Not to Overpackage: AI for Sustainability in Hellofresh's Service Supply Chain

Evelyn Xiao-Yue Gong, Carnegie Mellon University, Pittsburgh, PA, United States, Michael Johnson

Overpackaging is a common challenge faced by meal kit services. For each box of meal kits delivered to customers, meal kit service providers must decide the type of liner materials and the quantity of freezer packs to place inside. These materials ensure the quality of the meal kits delivered; on the other hand, overpackaging leaves a large carbon footprint and imposes psychological burdens on many customers. As the world's leading meal kit company and integrated food solutions group, HelloFresh is committed to furthering the sustainable nature of its supply chain and decreasing its environmental footprint. One important step is to reduce packaging. While HelloFresh has an in-house thermal engineering team that builds the packaging guidelines with a large number of scientific experiments, artificial intelligence offers numerous possibilities for improvement. This paper introduces the Contextual Packaging problem, and investigates artificial intelligence solutions to mitigate overpackaging efficiently. We develop a contextual bandit algorithm that takes into account the weather, the conditions of transit, the box contents and other contextual information to adaptively make the packaging decision for each box. To accelerate online learning, we identify a number of structural properties of the contextual packaging problem and extract structural information from the abundantly available past delivery data. Our algorithm achieves theoretically optimal performance with an $\tilde{O}(\sqrt{T})$ regret bound where T is the horizon length. We test our algorithm on real delivery data from HelloFresh and identify points of overpackaging in the current guidelines.

3 - A Transformer-Based Approach to Choice Modeling: Capturing Substitution and Complementarity Effects

Salvador K. Dzimah, MIT Operations Research Center, Cambridge, MA, United States, Manuel Moran-Pelaez, Georgia Perakis

Many demand estimation methods tend to not consider both substitution and complementarity effects among items. The few methods that consider both effects do not address the problem of explicitly measuring each item's impact on the others' demands. This motivated us to propose a novel Transformer-based choice model to capture both effects. Our model integrates text, image and categorical product features. Its architecture enforces an additive decomposition of each item's sales into a baseline plus contributions from other items. Our proposed model captures rich interactions while being interpretable due to its additive structure. Furthermore, the model generalizes to new products. We tested the model on real-world data. It successfully detects the underlying cross-item effects and achieves a 10% reduction in wMAPE compared to alternative methods that ignore these effects. The additive structure allows us to not only detect complements and substitutes, but also to measure the effects quantitatively and provide actionable insights for retailers.

4 - Managing Product Availability in Rental Subscriptions

Lennart Baardman, University of Michigan, Ann Arbor, MI, United States, Xuening Wang

For rental subscription services, managing product availability is a crucial operational challenge. When products are frequently unavailable, subscribers face a limited assortment that lacks variety and leads many to churn. We analyze data from a clothing rental subscription service to better understand customer attrition. Using machine learning, we find that an important contributor to churn is the customer's perception of limited variety in available clothing styles. One way to address this challenge is through better inventory management. In current practice, styles are shown to customers only when fulfillment can be guaranteed. In contrast, we develop inventory management policies that balance the trade-off between style display and order fulfillment. These policies aim to improve product availability while maintaining reliable delivery. We demonstrate that our approach outperforms the existing practice, both through theoretical bounds and through numerical simulations.

Building B Level 3 B312

Powering the Future: Innovations in Electric Vehicles, Energy Storage, and Renewable Generation

Invited Session

MSOM: Sustainable Operations

Chair: Yangfang Helen Zhou, Singapore Management University, Singapore, 228492, Singapore

1 - Impact of Energy Storage on Electricity Prices and Carbon Emissions

JIN-YANG HU, Duke University, Durham, NC, United States, Kevin Shang, Can Zhang

Energy storage serves as a practical solution to address the challenges arising from the high penetration of renewable energy sources in the electricity system. In this study, we analyze the role of energy storage, its impact on prices and emissions, and provide insights with significant policy implications.

2 - Battery Operations in Electricity Markets: Strategic Behavior and Distortions

Jerry Anunrojwong, University of Washington, Seattle, WA, United States, Santiago Balseiro, Omar Besbes, Bolun Xu

Electric power systems are evolving to accommodate intermittent renewable sources and storage technologies like batteries. As privately-owned batteries gain prominence, key questions arise: How do they behave in electricity markets, and how does their strategic behavior differ from that of centrally operated batteries? We propose an analytically tractable model that captures salient features of the highly complex electricity market. We derive in closed form the resulting battery behavior and generation cost in three operating regimes: (i) no battery, (ii) centralized battery, and (iii) decentralized profit-maximizing battery. We identify three distortions in decentralized battery behavior: (1) quantity withholding, i.e., discharging less than centrally optimal; (2) shift from day-ahead to real-time, i.e., postponing some discharge

from day-ahead to real-time; (3) reduction in real-time responsiveness, i.e., discharging less in response to smoothing real-time demand than centrally optimal. We quantify efficiency loss using the Price of Anarchy metric and show that the cost of strategic behavior is always bounded between $\$9/8\$$ and $\$4/3\$$. That is, incentive misalignment always exists, but it is bounded even in the worst case. We calibrate our model to real data from Los Angeles and Houston. Lastly, we show that competition is effective at reducing distortions, but many market power mitigation mechanisms backfire, leading to higher total cost. This work offers a framework for analyzing and quantifying market power in battery operations. It underscores that while battery market power does pose a concern, its negative impact is limited compared to the overall system benefits of sufficient battery capacity.

3 - Aggregator Business Model for Vehicle-to-Grid Services

Yangfang Helen Zhou, Singapore Management University, Singapore, Singapore, Meichun Lin, Owen Wu, John Pang

The rapid growth of electric vehicles (EVs) creates a major opportunity for vehicle-to-grid (V2G) services, where EVs discharge electricity back to the grid during peak demand. Since an average vehicle is idle over 95% of the time, EVs can potentially act as mobile storage to reduce reliance on costly, high-emission peak power plants. We propose a business model where EVs participate in V2G only a few times per year—aligned with peak demand days—ensuring minimal battery wear and preserving warranties from EV manufacturers. Even with such limited use, the collective impact from a growing EV base can be substantial. An aggregator coordinates drivers, participates in the electricity market, and compensates drivers while retaining profits or maximizing social welfare.

We build a two-stage stochastic model. In the first stage, the aggregator offers a reward menu based on the number of V2G services, and then the drivers choose their participation level based on their inconvenience costs. In the second stage, the aggregator solves a stochastic dynamic program to determine the number of V2G service reserves to use in each period, given the electricity demand and the remaining reserve.

We characterise the optimal reward menu design and show that it can vary non-monotonically as the number of services increases. Using real electricity price and demand data, we demonstrate the model's economic and environmental benefits, benchmarking with common approaches.

4 - Optimal Charging Decisions for Battery Swap Stations Under Demand Charge

Zimeng Li, Zhejiang University & City University of Hong Kong, Hangzhou, China, People's Republic of, Zhankun Sun, Quan Yuan

Battery swap stations mitigate electric vehicle range anxiety by enabling rapid replacement of depleted batteries. Our study investigates the optimal charging decisions for a battery swap station utilizing both grid and renewable energy. Our model incorporates stochastic customer arrivals, uncertain renewable generation, and time-varying electricity prices. The objective is to minimize total electricity bill (cost based on energy consumption and peak demand charges) and customer waiting cost by optimizing charging decisions. We formulate this as a finite-horizon dynamic programming problem and prove that the optimal charging policy is of threshold type. We find the optimal charging quantity is nonlinear with respect to the current demand charge. To tackle the computational complexity of the high-dimensional model, we propose a deep reinforcement learning method, informed by the threshold structure, to efficiently compute the optimal charging policy.

Dynamic Decision Making under Uncertainty: Models, Signals, and Experiments

Invited Session

Revenue Management

Chair: Zhe Liu, Imperial College London, London, United Kingdom

1 - Reformulations of Approximate Linear Programs for Finite-Horizon Markov Decision Processes

Jiannan Ke, Wuhan University, Wuhan, China, People's Republic of, Dan Zhang, Huan Zheng

We establish reformulations of approximate linear programs (ALPs) for a class of finite-horizon Markov decision processes (MDPs). These reformulations are either equivalent formulations or relaxations of the original ALPs. Our main result is established via constraint reformulations and duality arguments. In particular, it allows us to find equivalent reformulations of ALPs by checking a strong duality condition. We apply the framework to network revenue management and the finite-horizon restless bandit problem. For network revenue management with and without customer choice, we provide new, simplified proofs for the main results in Vossen and Zhang (2015) under the usual assumption of a binary consumption matrix. When the consumption matrix is non-binary, we establish new upper bounds under both affine and SPL approximations. For the finite-horizon restless bandit problem, we establish an equivalent reformulation under the assumption of a unit cost for pulling each arm and a relaxed upper bound when the cost is more general. A numerical study shows that the quality of the bounds and heuristic policies of the reformulations are competitive with alternative solution methods but at substantially reduced computational cost. Our work applies to a broad class of finite-horizon MDPs and has potential applications to many practical problems.

2 - Dynamic Persuasion Strategies for Mitigating the Spread of Fake Content

Wenjuan Li, HKUST Business School, Hong Kong, China, People's Republic of, Dongwook Shin

We examine how digital content platforms can design signaling mechanisms to shape consumers' engagement with potentially fake content. Initially, the platform and consumers face uncertainty about content veracity, but the platform can conduct random inspections to verify it. Based on inspection results, the platform strategically sends signals to consumers to ultimately maximize revenue. We analyze the structural properties of optimal public and private policies. Our findings show that both policies disclose inspection results with strategic delays, which enhances platform revenue but also increases consumers' exposure to fake content. Furthermore, unlike the optimal public policy, we find that the optimal private policy selectively discloses the inspection results to some consumers; consequently, the optimal private policy generates higher revenue than the optimal public policy but significantly undermines consumer welfare. We explore various strategies to reduce the spread of fake content while ensuring profitability. We find that enhancing the platform's inspection capability boosts the platform's profits but fails to curb the spread of fake content. Alternatively, our analysis suggests that implementing subscriptions and government penalties can effectively reduce fake content while enhancing the platform's revenue.

3 - Dynamic Decision Making with Operational Data Analytics

J Shanthikumar, Purdue University, WEST LAFAYETTE, IN, United States, Qi Feng, Yang Yang

We consider dynamic decision making with limited knowledge of the reward distribution. Under a parametric setting we show that a uniformly optimal data integrated dynamic policy can be derived for some classes of inventory and revenue management problems. We will use a simple revenue management problem to illustrate the basic idea.

4 - Optimal Resource Allocation in the Experiment-Rich Regime

Fenghua Yang, University of Michigan, Ann Arbor, MI, United States, Stefanus Jasin, Dae Woong Ham

Motivated by the large-scale experimentation practices of modern companies, we examine the problem of optimally allocating a fixed N number of customers across M concurrently running A/B testing experiments. While previous literature focuses on optimal allocation under a minimax framework minimizing mean squared error (MSE), we extend previous results under a new hypothesis testing framework that is also managerially relevant for decision making. Specifically, instead of minimizing MSE, we minimize type-2 error while always maintaining a valid type-1 error control. We provide optimal allocation results under two distinct cases: known variances and unknown variances. We find that minimizing MSE does not necessarily minimize type-2 error, especially under the case when the gap of minimum detectable effect is large. Extending our analysis to objectives beyond minimax, we show that, once the total sample size is sufficiently large, the asymptotically optimal allocations under the weighted-minimax and weighted-average criteria share the similar structure.

Chair: Mingxi Zhu, Georgia Institute of Technology, Atlanta, GA, 30033, United States

1 - Data-Driven Contextual Pricing with Semi-Parametric Models**Xiangyin Chen, Cornell University, Ithaca, NY, United States, Li Chen, Meng Qi**

We introduce a unified framework for the data-driven revenue-maximizing contextual pricing problem. Along with available contextual features, we consider two types of data: (1) observed customer valuations (also referred to as willingness-to-pay) and (2) customers' binary purchase data and posted prices, without knowledge of the prior pricing policy. We assume a semi-parametric model of customer valuation with a log-linear function of contextual features and a distribution-free noise term. This model enables an elegant solution for the optimal pricing policy that separates the dependencies of the contextual features and the noise term. Leveraging this solution structure allows us to develop efficient algorithms for the above two data settings. We show asymptotic optimality and finite-sample performance guarantees for these algorithms under general, estimator-agnostic conditions. Finally, we conduct comprehensive numerical experiments with both synthetic and real data. Tested on synthetic data, our algorithms demonstrate superior performance with various underlying distributions of the noise term. Applied to a real-world online auto loan dataset, our algorithms outperform commonly adopted state-of-the-art benchmarks.

2 - Market Power OR Data Power: when Do Competitors Choose to Collaborate?**Kaiwen Li, University of Southern California, Los Angeles, CA, United States, Mingxi Zhu**

This paper studies how the interplay between market power and data volume shapes firms' incentives to collaborate via federated learning (FL) platforms. While prior research often models information sharing as stylized signaling, it overlooks the complexity and scale of real-world customer data. Federated learning offers a practical alternative, allowing firms to jointly learn key market parameters without revealing raw data. We develop a game-theoretic model in which competing firms strategically decide whether to participate in FL. Our analysis identifies precise conditions under which data-rich or data-poor firms—depending on their relative market positions—choose to collaborate. We show that collaboration is more likely when data asymmetries outweigh market asymmetries, revealing a fundamental trade-off between data power and market power. These findings offer design principles for collaborative learning platforms in competitive markets and provide insights into when cooperation emerges among rivals.

3 - Building Agents for Healthcare Workflow Automation**Junze Ye, Stanford GSB, Stanford, CA, United States, Jiayi Wang, Mohsen Bayati**

We present an agentic framework for the automation of clerical and diagnostic tasks in healthcare, and a data-efficient way of finetuning an LLM to improve its performance on such task. An MDP model is presented to capture the sequential decision-making nature of such a workflow, and we validate the effectiveness of our approach on both real-world and synthetic data.

4 - AI and Machine Learning at Scale in Etsy's Marketplace**Salomón Wollenstein Beteck, Etsy, Washington DC, DC, United States**

How does a global marketplace for unique and creative goods harness the power of artificial intelligence? In this session, we explore how Etsy leverages cutting-edge machine learning and data science to enhance search relevance, recommendation systems, pricing strategy, and fraud detection—while preserving the human touch at the heart of its community. Featuring an industry expert from Etsy, this talk offers a behind-the-scenes look at the real-world challenges and solutions in deploying AI at scale in a two-sided marketplace. Attendees will gain insights into how Etsy balances personalization, fairness, and business objectives using applied ML, and what it takes to translate research into production in a dynamic e-commerce environment.

1 - Beyond $O(\sqrt{T})$ Regret: Decoupling Learning and Decision-Making in Online Linear Programming**Wenzhi Gao, Stanford University, Stanford, CA, United States, Dongdong Ge, Chunlin Sun, Chenyu Xue, Yinyu Ye**

Online linear programming plays an important role in both revenue management and resource allocation, and recent research has focused on developing efficient first-order online learning algorithms. Despite the empirical success of first-order methods, they typically achieve a regret no better than $O(\sqrt{T})$, which is suboptimal compared to the $O(\log T)$ bound guaranteed by the state-of-the-art linear programming (LP)-based online algorithms. This paper establishes a general framework that improves upon the $O(\sqrt{T})$ result when the LP dual problem exhibits certain error bound conditions. For the first time, we show that first-order learning algorithms achieve $o(\sqrt{T})$ regret in the continuous support setting and $O(\log T)$ regret in the finite support setting beyond the non-degeneracy assumption. Our results significantly improve the state-of-the-art regret results and provide new insights for sequential decision-making.

2 - On the Role of Curricula in the Decentralization of Service Delivery at Scale**Christopher Ryan, University of British Columbia, Vancouver, BC, Canada**

We discuss several case studies of service organizations using decentralization – mediated by curriculum development – in their process to reach scale. We will draw conclusions about the important operational role curriculum development can play in scaling service operations and offer an outline for future potential research.

3 - Dynamic Pricing for Last-Mile AI Automation: a Data-Driven Approach with Temporally Shrinking Choice Sets**Jingwen Tang, University of Miami, Coral Gables, FL, United States, Shuai Hao, Yuqian Xu, Cong Shi**

Motivated by one company offering autonomous on-demand delivery service, we study the dynamic pricing problem for the delivery time windows with capacity constraints. We formulate the problem into a multiproduct pricing problem, with a shrinking choice set, and the consumer choice is captured by an MNL model. To overcome the challenge raised by the diminishing delivery time windows, we decompose the system into multiple subsystems, which are linked with the capacity constraints. We propose a heuristic pricing strategy and show its asymptotic optimality in revenue as the problem scale (customer arrival rates, capacities) increases. We show the proposed strategy increases the revenue significantly compared to the current pricing policy by numerical experiments using the real data of the company. The method not only provides the practitioners with a practical pricing strategy with asymptotic optimal performance but also lends insights into other similar problems with varying choice sets.

4 - Evaluating Scheduling Policies with Lower Bias: An Arrival-Based Approach for Switchback Designs**Jierui Zuo, Tsinghua University, Beijing, China, People's Republic of, Jinglong Zhao, Zijie Zhou**

We propose an arrival-based estimator for switchback experiments designed to compare scheduling policies—specifically First-Come-First-Serve (FCFS) and Shortest-Job-First (SJF). Under a stationary workload assumption, where job arrival and job length distributions remain fixed, the commonly used naive estimator exhibits systematic bias arising from interactions among job arrival patterns, scheduling decisions, and queue dynamics. Our arrival-based estimator explicitly incorporates job arrivals to correct for this bias. We provide theoretical analysis demonstrating that our estimator achieves strictly lower expected bias compared to the naive estimator.

Simulation results further confirm that the arrival-based estimator yields more accurate and reliable comparisons of scheduling policies. Our method is applicable in many practical applications, such as LLM inference, where precise policy evaluation is critical for performance optimization.

Dynamic Matching and Resource Allocation

Invited Session

Auctions and Market Design

Chair: Süleyman Kerimov, Rice University, Houston, TX, United States

Co-Chair: Sophie Yu, The Wharton School of the University of Pennsylvania, Philadelphia, PA, United States

1 - Courier Ranking and Pricing

Matias Romero, Columbia Business School, New York, NY, United States, Hongyao Ma, Will Ma

On-demand delivery platforms typically fulfill orders by sending sequential take-it-or-leave-it offers to couriers, specifying both the job and the payment. This process involves ranking couriers and setting payments along the sequence of offers. In practice, these decisions are often made by different teams, each focusing on a single lever, which raises the question of how ranking and pricing interact. We study a parsimonious model that captures this interaction, where the platform knows both the value of matching each courier to a job and the acceptance probability induced by any payment. Our findings reveal that independently optimized decisions can lead to inefficiencies, and we show that simple policies achieve global optimality in important cases.

2 - Online Selection with Uncertain Disruption

Yihua Xu, Rice University, Houston, TX, United States, Süleyman Kerimov, Sebastian Perez-Salazar

In numerous online selection problems, decision-makers (DMs) must allocate on the fly limited resources to customers with uncertain values. The DM faces the tension between allocating resources to currently observed values and saving them for potentially better, unobserved values in the future. Addressing this tension becomes more demanding if an uncertain disruption occurs while serving customers. Without any disruption, the DM gets access to the capacity information to serve customers throughout the time horizon. However, with uncertain disruption, the DM must act more cautiously due to risk of running out of capacity abruptly or misusing the resources. Motivated by this tension, we introduce the Online Selection with Uncertain Disruption (OS-UD) problem. In OS-UD, a DM sequentially observes n non-negative values drawn from a common distribution and must commit to select or reject each value in real time, without revisiting past values. The disruption is modeled as a Bernoulli random variable with probability p each time DM selects a value. We aim to design an online algorithm that maximizes the expected sum of selected values before a disruption occurs, if any.

We evaluate online algorithms using the competitive ratio. Using a quantile-based approach, we devise a non-adaptive single-threshold algorithm that attains a competitive ratio of at least $1-1/e$, and an adaptive threshold algorithm characterized by a sequence of non-increasing thresholds that attains an asymptotic competitive ratio of at least 0.745. Both of these results are worst-case optimal within their corresponding class of algorithms.

3 - Optimality of Random Regular Graphs in Sparse Operations Designs

Xiaochun Niu, Duke University, Durham, NC, United States, Weijia Li, Yehua Wei, Jiaming Xu

The problems of designing sparse graphs arises frequently in resource allocation and operations research. For example, designing sparse flexible processes is widely used to effectively handle uncertain demand in production systems. Here the goal is to construct the sparsest bipartite graph between supply and demand sides, while achieving at least $(1-\epsilon)$ of the maximum sales of a fully flexible system. In addition, in middle-mile delivery operations, designing sparse subgraphs that sustain large matchings after random node deletions helps maintain predictable delivery routes. In this context, the goal is to design the sparsest graph whose maximum matching size is at least $(1-\epsilon)$ times that of the fully connected graph.

There has been a growing literature studying graph designs for both problems, where the performance of K -clusters, K -chains, and Erdős-Rényi graphs have been extensively analyzed. However, optimal sparse graph designs have remained an open question. In this paper, we prove that random d -regular graphs achieve $(1-\epsilon)$ -optimality for both problems. Specifically, its node degree d matches the lower bound on the average node degree required for any graph to achieve $(1-\epsilon)$ -optimality, thereby establishing the optimality of random d -regular graphs in these sparse design problems.

We also provide optimal bounds on the average node degree for graph designs involving geometric structure, such as K -chains and one-dimensional random geometric graphs, which characterize the location or feature vectors of nodes. Numerical experiments are included to enhance our theoretical findings.

4 - Matching Queues with Strategic Agents

Hossein Dabirian, University of Michigan, Ann Arbor, MI, United States, Saif Benjaafar, Brian Denton, Mustafa Akan, Philipp Afèche

We consider a two-sided queue where agents (e.g., customers and service providers) arrive continuously over time to each side, seeking to be matched with each other. In deciding whether to join the queue, agents are sensitive to the reward they earn upon matching and the cost incurred while waiting. It is well known that self-optimizing behavior does not maximize overall welfare in one-sided queues [Naor, 1969]. We extend this result to two-sided queues and propose a tolling strategy to align individual incentives with the welfare-maximizing strategy. In particular, we show that this may involve imposing a fee on one side (charging a positive price) while offering a subsidy for the other (a negative price). In contrast to results for one-sided queues, we show that the socially-optimal limits on queue sizes may be smaller or larger than those under self-optimization. We also characterize the price of anarchy, providing a tight bound.

5 - Managing Reusable Resources with Continuous Arrivals and Discrete Usage

Yun-Tung Kuo, Duke University, Durham, NC, United States, Cong Shi, Yehua Wei

In the hotel and car rental industries, resources are reusable, and the usages of these resources are often reserved in advance. While extensive research exists on managing reusable resources, a critical yet often overlooked feature in these industries is their dual time-scale dynamic. Specifically, reservation arrivals occur continuously over time, whereas usage times, characterized by fixed check-in and check-out times, are discrete.

We propose a dual time-scale dynamic model to seek to understand how reusable resources can be efficiently managed in the presence of advanced reservation arrivals. Surprisingly, while the dual time-scale dynamic disrupts the stationarity of usage requests, it enables the model to be closely approximated by offline resource allocation problems. This insight allows us to develop a state-dependent admission policy that achieves an optimality scaling superior to existing approaches that do not account for the dual time-scale feature. Our findings demonstrate that embracing the dual time-scales not only overcomes challenges but also strengthens theoretical guarantees, thus unlocking new strategies for managing reusable resources.

1 - Change Points in Functional Time Series Using Combinations of Strong Harmonics: Applications to Measuring Social Media Impacts of Sponsoring Large Sporting Tournaments

Moinak Bhaduri, Bentley University, Waltham, MA, United States

Discrete time series, owing to interrupted sampling, do not make provisions for a variable's existence in the intervening space between adjacent time points. The problem becomes especially acute for high-frequency data, such as (positive, negative, neutral) tweets of companies that lend their sponsorship to large sporting events like the US Open. In this talk, we examine how non-functional versions of common statistical objects like principal components upgrade to their functional counterparts and help us with the analogous tasks in functional settings: detecting change-points, for instance. We deploy inner products of crucial harmonics to query full functions (instead of parameters) and test whether between companies that do and do not sponsor the large events such as the US Open, break points occur at similar times around the tournament, and are of similar intensities. Thanks to our PhD student Shardul Wartikar for collecting sentiment data on tweets for sixteen sponsoring and sixteen non-sponsoring companies.

2 - Designing a Persuasion-Aware Smishing Detector for Evolving Threats

Chen Zhong, The University of Tampa, Tampa, FL, United States, Wei Xie

Smishing, or SMS-based phishing, continues to evolve as attackers increasingly exploit large language models (LLMs) to generate varied and convincing messages that alter tone, language, and keywords. This adaptability creates a significant gap: the lack of effective, explainable detection systems that can adapt to different smishing styles and strategies. Addressing this gap, we adopt a design science method to design and develop an effective smishing detection system grounded in persuasion theory. Building on our prior work, where we manually analyzed and coded 934 smishing messages according to persuasive techniques, this study leverages that dataset to train a machine learning model capable of identifying these strategies. Specifically, we implemented a RoBERTa-based classifier to detect persuasion cues with high accuracy. To promote transparency and foster user trust, we integrated Explainable AI (XAI) techniques that highlight which textual features contribute to the model's decisions. This feature provides users with meaningful explanations that can support long-term learning and awareness. Furthermore, we explore the tradeoff between accuracy and explainability, emphasizing the importance of a balanced approach that maintains detection performance while offering interpretable results. Our work contributes a replicable method for smishing detection grounded in theory and user-centered design, offering practical implications for both researchers and cybersecurity practitioners.

3 - Influenced by Influence: the Role of Social Media In Financial Knowledge Gaps

Jinglin Hu, University of Florida, Gainesville, FL, United States, Zefeng Bai, Ying Wang, Zimou Xiang

As more people rely on social media for financial advice, concerns have grown over its impact on individuals' understanding of personal finance. This study examines the relationship between social media use and financial knowledge disparity-- the gap between subjective and objective financial knowledge. Using data from the 2018 and 2021 waves of the National Financial Capability Study (NFCS), we find that individuals who seek investment advice on social media exhibit significantly greater financial knowledge disparity. Interestingly, the disparity is even more pronounced among individuals with a background in financial education. Our follow-up analysis confirms that greater financial knowledge disparity is associated with a higher likelihood of undesirable financial behaviors, including credit card misuse, early retirement withdrawals, and delayed mortgage payments.

These findings underscore the need for more effective, targeted financial education and stronger oversight of online financial content. By identifying vulnerable populations and the risks associated with financial knowledge disparity, our study can help policymakers, educators, and social platforms develop more informed interventions to encourage responsible financial behavior in this digital era.

4 - Corporate DEI Messaging on Social Media: Effects of Authenticity and Political Ideology on Consumer Engagement

Lingshu Hu, Washington and Lee University, Lexington, VA, United States, Weilu Zhang, Rui Sun, Detelina Marinova, Nathanael Seife

In recent years, brands and companies have renewed their commitments to diversity, equity, and inclusion (DEI) in response to evolving societal expectations. However, DEI-related content can be controversial and highly polarized, meaning its effects on consumer digital engagement may vary depending on the context. Drawing on Twitter data from approximately 500 U.S.-based firms, this study investigates the impact of engaging with DEI-related issues as part of corporate social media strategy. Specifically, we examine how political ideology and message authenticity influence the effectiveness of DEI-related tweets.

1 - Fulfillment Scheduling with a Concave Shipping Cost Structure

Liangzi Zhu, University of Maryland, College Park, MD, United States, Zhi-Long Chen

We study a fulfillment scheduling problem under a nondecreasing concave shipping cost structure. Unlike traditional linear cost models, our shipping cost function more closely reflects the real-world delivery cost. Each order must be processed first and then delivered to its respective customer by a committed deadline. An unlimited number of homogeneous vehicles is available for delivery, each with a capacity for a fixed number of orders. Our goal is to find a fulfillment schedule that minimizes the total delivery cost while ensuring that all order deadlines are met.

We analyze different cases in this study. With one customer, one processing line, and orders having agreeable processing times and deadlines, the problem can be solved to optimality by a dynamic programming algorithm in polynomial time. In addition, with multiple customers, identical parallel processing lines, and orders having non-agreeable processing times and deadlines, this problem is strongly NP-hard. We tackle this case using a column generation based heuristic to obtain near-optimal solutions.

2 - Robust Optimization in Generalized Project Networks

Siyuan Chen, The Hong Kong Polytechnic University, Hong Kong, Hong Kong, Nicholas Hall, Miao Song

The growing prevalence of project management as a business process is matched by its growing range of applications. Notably, modern projects are characterized not only by customary task time uncertainty, but also by uncertainties about their scope and constraints than traditional ones. However, research has so far not incorporated several of these fundamental uncertainties into project optimization. We address this deficiency by incorporating the modern project realities of (a) uncertain full or partial task rework, (b) the unexpected arrival of new tasks, (c) uncertainty in the existence of task precedence relationships, (d) probabilistic branching between alternative plans, and (e) uncertain availability or feasibility of contingency plans, into a general project network model. This model minimizes the total of plan evaluation and plan execution costs as well as expected tardiness relative to a defined makespan target. The model is solved by backward dynamic programming, using the sequential evaluation of contingency plans to define stages. The evaluation of tardiness at the terminal stage is accomplished by a distributionally robust optimization model. A computational study shows that the overall model is solvable within reasonable running time for up to 150 project tasks. We also use sensitivity analysis to identify insights for projects

managers. Our work expands the range of project management applications for which optimization is realistically possible. A special case where each plan has no more than three contingencies is shown to be more efficiently solvable.

Key words: project management, uncertain scope and constraints, dynamic programming, distributionally robust optimization.

3 - Poisoned Apples: Project Team Experiential Diversity, Project Performance, and Voluntary Turnover in the Context of It and Consulting Services

Yunfan Wang, IE Business School, Madrid, Spain, Fabrizio Salvador, Emmanouil Avgerinos, Marco Caserta

Retaining skilled human capital is essential for project performance in knowledge-intensive businesses. To this end, firms can assign employees to experientially diverse project teams, providing them with learning opportunities that foster motivation and commitment to the firm. However, as learning increases employees' market value, it can paradoxically raise the risk of voluntary turnover. This conundrum is exacerbated when considering the effect of team experiential diversity on project performance: promoting diversity may create a more engaging work environment but is incompatible with having stable teams of specialists. In this study, we investigate the effect of team experiential diversity using data from 810 project teams, involving 3,139 employees, from a multinational consulting and IT services firm. We focus on team experiential diversity relative to customer experience (i.e., client experience diversity) and familiarity among team members (i.e., coworker experience diversity). We find that team experiential diversity increases project performance but has an inverted U-shaped relationship with voluntary turnover. Furthermore, we use the variables from our regression models to build predictive machine learning models for project performance and voluntary turnover. We find that after including the team experiential diversity variables, model accuracy increases for both models, further supporting their economic importance. With this paper, we contribute to broadening the focus of operations management research on project teams beyond project performance to include talent retention—a fundamental goal and concern for project managers in knowledge-intensive industries.

4 - Cost Optimization of Repetitive Project Scheduling with Integrated Material Ordering

Xiaoqi Lei, Huazhong University of Science and Technology, Wuhan, China, People's Republic of, Nanfang Cui

With the rapid growth of prefabricated construction, efficient material management and project scheduling have become critical challenges. Key materials like prefabricated components, concrete, and steel reinforcement involve substantial transportation and storage costs, significantly impacting overall project expenses. Since project scheduling and material ordering are interdependent, integrated optimization is crucial for cost efficiency. However, existing research on the Project Scheduling and Material Ordering Problem (PSMOP) focuses on general projects, neglecting repetitive projects which involve complex network relationships, work continuity constraints, etc.

This study analyzed the trade-offs between material ordering costs, inventory costs, and interval time costs in the **Repetitive Project Scheduling and Material Ordering Problem (RPSMOP)**. A **0-1 integer linear programming model** is formulated, optimizing activity start times and material ordering schedules to minimize overall costs. To solve the model, a **nested simulated annealing genetic algorithm (SAGA)** based on the encoding of activity start time was designed. Its core is to determine the activity time window and generate feasible solutions using different rules to handle the continuity constraints. The validity and superiority of the model and algorithm were verified through large-scale simulation and sensitivity analysis. The solution results for four different hypothetical scenarios show that under the condition of interruptible work, adjusting the start time of non-critical activities can obtain better project scheduling and material ordering plans. The sensitivity analysis of cost parameters shows that the algorithm optimization is mainly achieved by merging orders to reduce the number of orders.

5 - A Heuristic Approach to Scheduling Raw-Material Unloading at A Steelworks

Hansol Kim, Pohang University of Science and Technology (POSTECH), Pohang, Korea, Republic of, Seonggyun Hong, Byung-In Kim, Hae-Jin Sung, Hyeonon Wi

The raw-material unloading scheduling problem involves determining an efficient schedule for unloading iron ore and coal from ships at a steelworks equipped with six discrete berths. The complexity of this problem is heightened by several factors, including varying unloader capacities based on both unloader type and carried raw material brands, as well as eligibility constraints between berths and raw materials. Additionally, since the unloaded materials must be transported to designated storage yards via belt conveyor systems, where no two routes can simultaneously use a common conveyor link, the complexity of conveyor networks and transportation planning must also be considered. If a ship's unloading is completed later than its designated time, a demurrage cost is incurred. The objective of this scheduling problem is to minimize the total demurrage cost. However, due to uncertainties such as weather and wind speed, the unloading time of a ship cannot be precisely estimated solely from the material types, quantities, and unloader specifications. To address this, we propose a linear programming model to estimate ship unloading times. We also developed an iterative heuristic algorithm to efficiently solve the unloading scheduling problem. The proposed algorithm is evaluated using real-world data from the world's largest steelworks, demonstrating both its effectiveness and practical applicability. The algorithm is currently undergoing pilot testing at the steelworks.

6 - Integrated Optimization of Steel Grade Assortment, Production, and Inventory Planning

Gongshu Wang, Northeastern University, Shenyang, China, People's Republic of, Sibao Liu, Lixin Tang

In response to increasingly diversified and personalized market demands, the steel industry is shifting from traditional mass production to mass customization in order to enhance production flexibility, reduce costs, and better meet individual customer requirements. This study addresses the integrated optimization of steel grade assortment, production planning, and inventory control within a two-stage manufacturing system specifically configured to enable mass customization. The problem entails selecting appropriate steel grades for customer orders, determining production quantities for both intermediates and finished products, and managing intermediate inventories—aiming to minimize total costs while maximizing order fulfillment within delivery windows. The complexity arises from a two-level decision-making structure, where high-level decisions on steel grade assortment are interdependent with low-level production and inventory planning, creating intricate coordination challenges across stages. To address this, we formulate a mixed-integer programming model and develop a tailored metaheuristic approach. The method combines: (i) hierarchical optimization for constructing initial solutions, (ii) a fix-and-optimize strategy for re-optimization of decomposed variable blocks, and (iii) a kernel-based intensification mechanism that iteratively refines promising regions of the solution space. Computational experiments on synthetic instances demonstrate the effectiveness of the proposed approach and offer managerial insights into achieving a balance between cost efficiency and order responsiveness in customized steel production.

7 - Toward a Resilient Project Configuration and Planning: A Proactive-Reactive Optimization Approach Under Complex Disruptions

Julien Maurice, Georgia Institute of Technology, Atlanta, GA, United States, Jihye Jung, Benoit Montreuil, Simon Kwon, mahsa mahdavisarif

While traditional project planning focuses on assigning start times to activities, it often relies on simplified, independent activity configurations (small set of predefined options that only affect individual durations or costs). In contrast, project configuration extends this scope by accounting for interdependencies between activity configurations throughout the project lifecycle (e.g. production rate, storage and transportation strategy, or resource level). This approach is particularly valuable in complex projects, such as in the construction industry, where activities are highly interdependent, subject to disruptions and involve multiple stakeholders requiring dynamic decision support.

However, most existing methods in the literature simplify these dependencies and consider only basic disruptions scenarios. To address this gap, we propose a Proactive-Reactive Project Configurator and Planning that supports both baseline planning and adaptive reconfiguration.

Our framework first builds a baseline configuration using a mixed-integer programming (MIP) model that determines each activity's execution mode and start time, with the objective of minimizing total project cost and completion time. Then, different levels of disruptions under various scenarios are simulated to reflect real-world uncertainties. These scenarios are clustered based on their impact on model outputs and decision variables for different stakeholders. This method enables the identification of recurring reconfiguration strategies and supports robust, resilient reconfiguration of the project time and cost.

We demonstrate the applicability of our approach on a complex construction project with a modular and distributed structure. We also analyze the resiliency of the project configuration on adapting to disruptions and guiding decision-making across both proactive and reactive phases.

1 - Development and Cost Effectiveness of a Referral Process for Integrated Medical and Dental Care

Tasfia Mubashshirath Roshnee, The Pennsylvania State University, University Park, PA, United States, Paul Griffin

In the US, there has been a lack of integration between medical and dental care for chronic conditions such as Type 2 Diabetes Mellitus (T2DM). There is an opportunity to improve patient outcomes through better coordination. For example, tooth scaling and root planning for patients with periodontal disease has been shown to significantly reduce HbA1c levels. We develop a patient referral model and consider its cost effectiveness for patients with T2DM. We first use a Bayesian network (BN) model to predict disease progression and complication risks among T2DM patients utilizing longitudinal patient data from electronic health records (EHR) to identify high-risk T2DM patients who would benefit from timely dental screening and intervention through better glycemic control and reduced likelihood of developing a diabetic-related complication such as neuropathy or diabetic retinopathy. We consider clinical, demographic, and behavioral variables to provide patient-specific risk assessments for periodontal disease. We then consider the cost-effectiveness of the proposed referral strategy from the payer perspective. We conduct sensitivity analyses and compare the results with actual observed clinical outcomes. The overall goal is to develop a framework to improve clinical outcomes and optimize resource allocation by effectively preventing and mitigating diabetes-related complications.

2 - A Cross-Continental Investigation of Race-Based Variations in Leukemia Drug Toxicity Using OpenFDA Pharmacovigilance Data

Hossein Amini, Washington University in St. Louis, Saint Louis, MO, United States, Ali Abbasi

This study investigates the diversity of responses to FDA-approved leukemia treatments by analyzing data from the OpenFDA adverse event report system. We examine a comprehensive dataset comprising over 300,000 safety reports submitted between 2004 and 2022, allowing us to assess trends over time and across various global regions. Utilizing a range of analytical methods, we identify patterns in adverse reactions and explore whether the timing of side effects differs among various racial groups.

Our research findings indicate that certain populations may experience more pronounced or earlier onset of side effects from leukemia medications. For example, specific racial groups exhibit higher rates of particular adverse reactions in designated regions, and we have observed variations in the timing of side effect onset among other demographics. These patterns emphasize the necessity of considering racial and geographic factors when evaluating drug safety and efficacy. Ultimately, our study underscores the imperative for more personalized approaches in the monitoring and management of leukemia treatment to promote improved and more equitable health outcomes globally.

3 - Temporally Feathered Radiation Therapy Planning

Aysenur Karagoz, Rice University, Houston, TX, United States, M. Soheil Hemmati, Andrew Schaefer

Intensity-modulated radiation therapy (IMRT) remains the standard-of-care radiation therapy technique for most head-and-neck cancer (HNC) patients. Despite the relatively high survival rate of HNC (65-75%), the survivors often suffer from post-treatment long-lasting side effects, which negatively affect their quality of life. In an IMRT-based treatment plan, the daily doses delivered to the tumor and organs-at-risk (OARs) remain fixed based on the premise that the one-day inter-fraction suffices for each OAR's recovery. However, a novel treatment planning approach, referred to as temporally feathered radiation therapy (TFRT), proposes variable daily dose delivery to the OARs, aiming at increasing the recovery time of OARs at the cost of receiving higher doses once a week. While initial implementations of TFRT have shown promising results in the clinic, they do not distinguish between the inherent radiobiological differences among OARs for HNC patients, thus prescribing longer, yet uniform recovery time for all OARs. By considering variable radiosensitivity profiles across multiple OARs for HNC radiation therapy, we develop a mixed-integer nonlinear program (MINLP) that computes specific recovery time for each OAR to minimize the toxicity burden to the patients. Our proposed MINLP leverages the linear-quadratic model, which predicts each OAR's survival from radiation-induced damages. Our model is further flexible in addressing specific prioritization of OARs based on the clinician's preferences. The result of our model indicates a lower overall toxicity burden when OARs with higher radiosensitivity have longer recovery times under the TFRT framework.

4 - Physician Workload and Medical Malpractice Liability: An Empirical Investigation

Denise Bergdolt, University of Pittsburgh, Pittsburgh, PA, United States, Prakash Mirchandani

Medical malpractice—professional negligence by healthcare practitioners resulting in patient harm—is a critical issue in the U.S. healthcare system, affecting thousands of stakeholders and carrying a financial impact of billions of dollars annually. We construct an extensive, national, retrospective database to examine how physician workload intensity impacts medical malpractice case intensity at a state-year level.

To investigate the relationship, we implement a generalized propensity score stratification method suited for continuous workload intensities. We find a concave relationship between the natural log of the workload intensity and case intensity. At low workload intensity levels, increases in workload intensity are associated with rising medical malpractice case intensity levels. Counterintuitively, beyond a tipping point, as workload intensity further increases, case intensity decreases.

We attribute the concave pattern to a shift in the relative dominance of the work stress and defensive medicine effects. As workload rises, physicians may experience increased stress, mental workload and burnout, all of which negatively correlate with medical setting job performance in the literature. Meanwhile, a different stream of literature illustrates that if physicians do not have sufficient time to inspect their patients, they are more likely to use defensive medicine, which leads to increased treatment documentation, ultimately decreasing the odds of medical malpractice conviction in court settings.

We conduct robustness checks using alternative model specifications, and sensitivity analysis to account for unobserved covariates. We discuss the practical and theoretical impact of our findings on medical malpractice mitigation, and propose future streams of research.

5 - Adaptive Behavior of Paramedics: Impact of Paramedic Crew Workload on Scene TIME Duration and Probability of Patient Transport

Maryam Zakeri, Alberta School of Business, Edmonton, AB, Canada, Armann Ingolfsson, Mohammad Delasay, Kenneth Schultz, Graham Vanderwater, Gerald Lazarenko, Jim Garland, Peter Helfrich

Emergency medical services (EMS) play a critical role in patient care, yet the variability in demand—by severity, timing, and location—makes capacity planning challenging. Paramedics must stabilize, treat, refer or transport patients while managing both physical and cognitive fatigue, which may influence their decision-making. This research explores how fatigue affects EMS crew decisions on scene. We develop a workload measure that represents of fatigue and employ statistical methods to establish a causal link between workload and scene outcomes. Specifically, we analyze scene time and transport decision across four call types: cardiac arrest, trauma, opioid overdose, and influenza-like illness. Our findings provide insights for optimizing EMS resource management and improving patient care efficiency.

Human and Societal Applications of AI

Contributed Session

Contributed

Chair: Guoxin Wang, Renmin University of China, Beijing, N/A

1 - Challenges and Safety of AI Applications

Young Lee, UL Solutions, Melville, NY, United States, Sudhi Sinha, Kenneth Boyce

Artificial Intelligence (AI) is driving transformative changes across industries by enhancing automation, predictive analytics, intelligent decision-making, and operational efficiency. However, the journey from AI development to real-world deployment is riddled with significant challenges. This presentation delves into two critical facets of AI adoption in the industrial sector: the multifaceted challenges that organizations encounter while implementing AI solutions and the paramount importance of AI system safety to ensure reliable, ethical, and secure functionality.

The talk covers the complexities of industrial AI development, including data collection and management, model selection, deployment scalability and system integration. These challenges not only impact the performance and success of AI applications but also raise concerns regarding trust, transparency, and accountability.

Furthermore, the presentation will address the risks linked to AI model robustness and reliability, the need for transparency and explainability, control and oversight mechanisms, biased decision-making, data privacy concerns, security vulnerabilities, regulatory compliance, and broader societal impacts. The talk examines how safety considerations are integral to addressing deployment challenges, forming a bridge between AI reliability, ethical responsibility, and regulatory adherence.

By exploring these interconnected themes, the talk aims to provide insights into the evolving landscape of AI adoption, highlighting the need for a balanced approach that embraces both innovation and responsibility in shaping the future of AI-powered industries.

2 - Real-Time Bilevel Contingency Scheduling via AI-Inspired Adversarial Search

Adam DeHollander, University at Buffalo, Buffalo, NY, United States, Moises Sudit, Mark Karwan, John Crassidis

We study a bilevel scheduling problem in which a “leader” must complete a set of interdependent tasks while an “adversary” can enact disruptive moves that delay task execution. This formulation captures a broad class of real-world contingency planning and resilience challenges. Solving the resulting bilevel optimization exactly is intractable in most instances. We adapt adversarial search techniques from board games such as chess (e.g., lower bounds, pruning, and transposition tables) to dramatically reduce the decision space. On benchmark instances, our AI-inspired solver demonstrated orders of magnitude improvement in the time to solve the problem and achieve near-optimal solutions by decreasing the decision space, making it practical for rapid, real-time planning.

3 - How Generative AI Reviews Shape Online Engagement

Wenyu Jiao, University of Science and Technology of China, Hefei, China, People's Republic of

Recent advancements in generative AI for content creation present significant opportunities to transform the online retail industry. This study examines the effects of generative AI-enabled reviews on customer experience and engagement. In collaboration with an e-commerce platform and using a quasi-experimental design, we find that generative AI-generated reviews enhance customer behavior by increasing both viewing time and purchase rates. However, they also lead to a reduction in customer engagement in the form of review contributions. Our analysis reveals that these AI-generated reviews are particularly effective in boosting sales within functional product categories and have a greater positive impact when a diverse set of reviews is available. Additionally, they significantly improve the experience of less experienced online shoppers. These findings offer valuable insights for e-commerce platforms implementing AI-powered content creation tools.

4 - Extracting Policy Intelligence from Public Data Sources : LLMs as Policy Assistants

Giyun Kim, Seoul National University, Seoul, Korea, Republic of, Sanghyun Park, Dongyoon Shin, Jungeun Kim, Sungjoo Lee

Developing domain-specific frameworks for large language model (LLM) applications has been widely studied to enhance research efficiency across various fields. As policy planning requires detailed analysis of reliable sources, LLM applications have significant potential to enhance analytical efficiency. Therefore, we propose a novel LLM application framework designed for policy planning that reduces the time and resources required for analyzing global policy trends and their comprehensive content, including goals, implementation processes, outcomes, and causal relationships. First, a systematic collection and evaluation of datasets to identify reliable sources of global policy information that could serve as valuable references for policymakers was conducted. This process involved indicator development for data quality assessment in terms of reliability, relevance, completeness, and timeliness. We then categorized types of policy planning based on an in-depth analysis of previous policy documents, establishing key content requirements for each category. Subsequently, the fine-tuning and retrieval-augmented generation (RAG) approaches for the datasets were suggested and validated to efficiently extract required information from the collected datasets. We expect the framework to help policymakers effectively analyze global policy landscapes, identify policy implementation strategies along with their results, and derive valuable insights for policy planning across diverse contexts and challenges.

5 - Fast vs. Wise: Effect of Decision Speed and Quality on Users' Adoption of AI Advice

Guoxin Wang, Renmin University of China, Beijing, China, People's Republic of

Drawing on cue utilization theory, this research investigates how decision speed and quality affect users' adoption of artificial intelligence (AI) advice. Three experiments demonstrate that users exhibit higher adoption intention when AI decision speed or quality is high versus low, mediated by perceived intelligence and perceived risk. When decision quality is high, the positive impact of decision speed is attenuated. Importantly, task complexity and time pressure jointly moderate these relationships. Under high time pressure, users prioritize decision speed over quality regardless of task complexity, as speed becomes a dominant cue for AI competence. However, under low time pressure, task complexity determines cue utilization: for simple tasks, speed remains influential, while for complex tasks, quality becomes the primary determinant of adoption intention. The research extends cue utilization theory to human-AI interaction, demonstrating how situational factors shape the relative importance of AI performance cues. Practical implications include designing adaptive AI interfaces that emphasize speed indicators during time-pressured situations and quality indicators for complex tasks in reflective contexts, optimizing user adoption across diverse decision environments.

Uncertainty-Aware Surrogate Modeling and Optimization for Complex Systems

Invited Session

Quality, Statistics and Reliability

Chair: Kangan Chen, University of Wisconsin Madison, Madison, WI, United States

Co-Chair: Siqin Yang, Arizona State University, Tempe, AZ, United States

Co-Chair: Andi Wang, University of Wisconsin-Madison, Madison, WI, United States

1 - Exact Multistage Bayesian Optimization**Kangan Chen, University of Wisconsin-Madison, Madison, WI, United States, Siqin Yang, Hao Yan, Andi Wang**

This paper introduces the Exact Multistage Bayesian Optimization (EMSBO) algorithm for optimizing multistage experiment, where intermediate outputs serve as part of subsequent stage inputs. Unlike existing approaches that either ignore intermediate observations or rely on heuristic methods, EMSBO employs a dynamic programming formulation to exactly compute the expected utility of each stage considering all subsequent stages. The algorithm's utility functions are approximated through posterior Monte Carlo sampling and nearest neighbor interpolation. The theoretical bounds are established for the approximation error. Experimental results demonstrate that EMSBO outperforms existing methods like BOFN and CASCADE, particularly in early optimization iterations, while it maintains computational scalability for problems with up to 10 stages. The method's effectiveness stems from exploiting the sparse dependency structure inherent in multistage experiments, enabling exact solutions where broader look-ahead Bayesian optimization approaches become intractable. This makes EMSBO particularly valuable for optimizing complex sequential processes in scientific and engineering applications.

2 - Functional Approximated Multistage Bo: Reformation of Multistage Bo in RL Fashion**Siqin Yang, Arizona State University, Mesa, AZ, United States, Hao Yan, Zhenyu Kong**

Multistage experiments are commonly observed in industrial applications. While current composite Bayesian Optimization methods utilize intermediate results to provide better performance than standard BO, we propose a principled framework that reformulates multistage Bayesian Optimization as a Markov Decision Process. Under this formulation, we employ dynamic programming techniques with approximations to address the problem. Our Functional Approximated Multistage Bayesian Optimization (FAMBO) algorithm efficiently makes advantage of functional approximation and on-policy sampling. Empirical experiments show that our algorithm outperforms or at least performs considerably well compared to SOTA methods with much better performance in early stages and shorter computational time.

3 - Temporal Causal Representation Learning for Distributed Data**Jianhong Chen, northeastern university, Everett, MA, United States**

Causal representation learning, also known as causal discovery, has garnered attention for analyzing observational data because controlled experiments can be costly. In this setting, Bayesian Networks (BNs) are the standard score-based approach for learning causal diagrams. However, BNs capture only contemporaneous causal relations. To model time-lagged relations, researchers have extended BNs into Dynamic Bayesian Networks (DBNs). Traditionally, structure learning for Dynamic Bayesian Networks has been performed in a centralized fashion, requiring all data to be pooled in one location. However, in real-world settings, data are often distributed across multiple entities (e.g., companies) that wish to collaborate on network estimation while preserving privacy and security. Moreover, because clients may come from different sources, their data can follow disparate distributions, resulting in heterogeneity. To address these challenges, we introduce a federated personalized learning based method for estimating a Dynamic Bayesian Network from distributed heterogeneous time series data by incorporating a proximal operator as a regularization term. More importantly, our framework has been extended to tensor-like data, such as Electronic Health Records (EHRs). Since the tensor data can be considered as many frontal slices and decomposed into several meaningful components, also known as computational phenotype, we can learn the causal phenotype network without sharing the information of any slice. By leveraging PARAFAC2 decomposition, we introduce a joint-learning approach to infer the causal network. To the best of our knowledge, There is limited work in both research directions. Experimental results on synthetic and real-world datasets demonstrate that both our methods outperform state-of-the-art techniques.

4 - Deepoformer: Deep Operator Learning with Domain-Informed Features for Fatigue Life Prediction**Chenyang Li, New Jersey Institute of Technology, Newark, NJ, United States, Tanmay Kapure, Prokash Roy, Zhengtao Gan, Bo Shen**

Fatigue life characterizes the duration a material can function before failure under specific environmental conditions, and is traditionally assessed using stress-life (S-N) curves. While machine learning and deep learning offer promising results for fatigue life prediction, they face the overfitting challenge because of the small size of fatigue experimental data in specific materials. To address this challenge, we propose, DeepOFormer, by formulating S-N curve prediction as an operator learning problem. DeepOFormer improves the deep operator learning framework with a Transformer-based encoder and a mean L2 relative error loss function. We also consider Stüssi, Weibull, and Pascual and Meeker (PM) features as domain-informed features. These features are motivated by empirical fatigue models. To evaluate the performance of our DeepOFormer, we compare it with different deep learning models and XGBoost on a dataset with 54 S-N curves of aluminum alloys. With seven different aluminum alloys selected for testing, our DeepOFormer achieves an R2 of 0.9515, a mean absolute error of 0.2080, and a mean relative error of 0.5077, significantly outperforming state-of-the-art deep/machine learning methods including DeepONet, TabTransformer, and XGBoost, etc. The results highlight that our DeepOFormer integrating with domain-informed features substantially improves prediction accuracy and generalization capabilities for fatigue life prediction in aluminum alloys.

5 - Jump Gaussian Process Surrogate Modeling with High Dimensional Inputs**Yang Xu, University of Washington, Seattle, WA, United States, Robert Gramacy, Chiwoo Park**

Gaussian process regression (GPR) is a powerful surrogate-modeling tool that delivers principled uncertainty quantification but struggles with piecewise-continuous targets. The Jump Gaussian Process (JGP) addresses this by simultaneously learning local partitions and fitting independent GPs, yet in high dimensions sparse neighborhoods degrade its performance.

We introduce the Locally Mahalanobis Jump Gaussian Process (LM-JGP), a novel method for estimating piecewise continuous regression functions in high-dimensional input spaces. LM-JGP merges the discontinuity detection capability of Jump Gaussian Processes with a built-in local dimensionality reduction mechanism. Our approach employs region-specific projection matrices to capture subspace structure, coupled with latent jump indicators to identify regime changes. We develop a scalable variational inference algorithm that handles both inducing variables and jump indicators, and demonstrate superior prediction accuracy and uncertainty quantification on synthetic and benchmark datasets.

Advancements in Decision-Making for Reliability and Maintenance

Invited Session

Quality, Statistics and Reliability

Chair: Vipul Bansal, University of Wisconsin Madison, Madison, WI, United States

Co-Chair: Akash Deep, Oklahoma State University, Stillwater, OK, United States

1 - "Learning to Recognize the Unseen: A Meta-Learning Approach for Ood Detection in Manufacturing"

Zihan Li, University of Florida, Gainesville, FL, United States

Defect inspection plays a vital role in predictive maintenance for manufacturing systems such as batteries, bearings, and aircraft engines. While neural network (NN)-based methods have demonstrated promising performance in qualification tasks, they often rely on the assumption that the testing system shares the same manufacturing specifications and operational conditions as the training data. In practice, however, systems are frequently heterogeneous, and data availability for the system of interest is limited. This mismatch can significantly degrade model performance and reliability, especially in safety-critical applications.

To address these challenges, we propose a meta-learning-based approach for Out-of-Distribution (OOD) detection in defect inspection. Meta-learning, or “learning to learn,” enables models to quickly adapt to new tasks with minimal data, making it well-suited for heterogeneous manufacturing environments. This is particularly important in modern manufacturing settings where unseen operating conditions, new machinery, or environmental changes may arise. By focusing on OOD detection through meta-learning, our research aims to build more robust and trustworthy predictive models that can generalize beyond the closed-world assumption and maintain reliability under evolving real-world conditions.

2 - Two-Layer Multi-Agent RL for Scalable Fleet Maintenance Under Constraints

Ahmad Salehiyan, Oklahoma State University, Stillwater, OK, United States, Akash Deep

Managing large fleets under constraints on crews, parts, and budgets requires scalable and coordinated maintenance planning. This work presents a two-layer, multi-agent framework for condition-based maintenance. At the lower layer, each asset is modeled as a Markov Decision Process (MDP) that tracks its own degradation and selects maintenance actions. At the upper layer, a central coordinator monitors the fleet, enforces constraints on resource usage and downtime, and provides high-level guidance. Both layers are trained jointly using an actor-critic reinforcement learning approach: the central agent maintains a shared critic, while each asset independently updates its actor. This architecture allows each asset to adapt to its specific condition while ensuring that fleet-level performance remains within budget and availability targets. We demonstrate our framework’s effectiveness with numerical experiments and a real-world fleet maintenance case study.

3 - Condition-Based Maintenance Planning for Partial Observable Multi-Component Systems

Han Hu, University of Wisconsin-Madison, Madison, WI, United States, Vipul Bansal, Shiyu Zhou

Condition-based maintenance (CBM) is a wide-used maintenance planning framework as it makes better-informed maintenance decisions based on system conditions. However, the prevalent existence of partial observability in various systems brings difficulty to CBM problems, especially those of complex systems. This paper addresses the challenge of CBM planning for partially observable large-scale systems with K -out-of- N configuration and economic dependencies. The computational intractability of directly applying Partially Observable Markov Decision Process (POMDP) approaches to such systems motivates our proposed Component-Wise POMDP (CW-POMDP) framework. By decomposing the system-level problem into component-level POMDPs while preserving economic dependencies, we develop efficient maintenance policies using the Successive Approximations of the Reachable Space under Optimal Policies (SARSOP) solver. Theoretical analysis establishes bounds on the optimality gap, while numerical experiments demonstrate that CW-POMDP consistently outperforms benchmark methods across varying system sizes, setup costs, and observation uncertainty levels. A turbofan engine fleet maintenance case study validates our approach’s practical effectiveness for real-world applications.

4 - Towards Failure-Mode-Aware Federated Prognostics: Selective Collaboration for Failure Time Prediction

Yuhan Hu, NC State University, Raleigh, NC, United States, Xiaolei Fang

Federated prognostics enable clients to collaboratively develop failure time prediction models while keeping each client’s data local and confidential. However, existing federated prognostic models face several challenges in real-world applications, particularly due to data heterogeneity across clients and high dimensionality of degradation signals. To address these issues, this talk introduces a three-step federated prognostic framework that facilitates efficient feature extraction and tailored model training while preserving data privacy. We first cluster machines with similar degradation patterns via a LASSO-based approach without centralizing raw data. Then, within each cluster, a federated data fusion method based on robust principal component analysis is applied to extract informative representations of degradation signals. Finally, each cluster utilizes the fused features to train a personalized prognostics model using log-location-scale regression. Numerical studies demonstrate the superior performance of the proposed model compared to existing methods.

5 - Tensor-Efficient High-Dimensional Q-Learning

Junyi Wu, University of Wisconsin, Madison, Madison, WI, United States, Dan Li

High-dimensional reinforcement learning faces challenges with complex calculations and low sample efficiency in large state-action spaces. Q-learning algorithms struggle particularly with the curse of dimensionality, where the number of state-action pairs grows exponentially with problem size. Current solutions include function approximation methods and neural network-based approaches like Deep Q-Networks, but these often suffer from instability and require extensive hyperparameter tuning. We propose Tensor-Efficient Q-Learning (TEQL), which applies low-rank tensor decomposition via block coordinate descent on discretized state-action spaces, incorporating novel exploration and regularization mechanisms. The key innovation is an exploration strategy that combines approximation error with visit count-based upper confidence bound to prioritize actions with high uncertainty, avoiding wasteful random exploration. Additionally, we incorporate a frequency-based penalty term in the objective function to encourage exploration of less-visited state-action pairs and reduce overfitting to frequently visited regions. Empirical results on large discrete control tasks demonstrate that TEQL outperforms conventional matrix-based methods and deep RL approaches in both sample efficiency and total rewards, making it suitable for resource-constrained applications, such as space and healthcare where sampling costs are high.

The Transforming Roles of AI In Economic Theory and Applications

Invited Session

Artificial Intelligence

Chair: Chenglong Zhang, Chinese University of Hong Kong, Shenzhen, Shenzhen, 518172

1 - Data-Driven Policy Learning for Continuous Treatments

Yue Fang, Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Chunrong Ai, Haitian Xie

This paper develops a framework for policy learning with continuous treatments using observational data. Unlike discrete treatment settings, continuous treatments pose greater challenges due to the need for nonparametric estimation of population welfare and the potential infinite-dimensionality of the policy space, often subject to shape constraints as usually considered in economic applications. To address these challenges, we propose an approximation-based approach that embeds the policy space into a sequence of finite-dimensional function classes, allowing scalable optimization and principled generalization. For a given policy, we estimate empirical welfare using kernel-based methods, and we handle both known and machine-learned propensity scores. In the latter case, we adjust the empirical welfare to correct for the bias introduced by estimating the propensity function with flexible machine learning models. Our method selects tuning parameters—such as bandwidths and policy space complexity—via data-driven procedures, enabling automation and adaptivity. We derive oracle inequalities that characterize the regret of the learned policy relative to the optimal one. As a key implementation, we integrate deep neural networks as a policy class to capture complex treatment-outcome relationships, demonstrating the applicability of our approach in high-capacity AI-driven models.

2 - Consumer-Led Data Sharing

Yifan Dou, Fudan University, Shanghai, China, People's Republic of, Xiaoyang Zhang

Serving as the cornerstone of the AI development, consumers’ data is receiving growing attention from firms and regulators. One of the recent legislation efforts in Europe is to enable consumers to initiate data-sharing between firms. This new paradigm introduces economic implications that remain largely unexplored in existing literature.

This paper employs a stylized model in which consumers can mandate the data-rich firm to share the data to the data-poor one. Our results indicate that consumer-led data sharing intensifies competition, which increases the aggregate consumer surplus and social welfare. However, it may also harm certain consumer segments, particularly those who are loyal to the data-poor firm, due to firm-side strategic price adjustments. These findings offer timely insights to understand the economic impact of new advances in the data regulation.

3 - Deep Learning for Double Auction

Chenglong Zhang, The Chinese University of Hong Kong, Shenzhen, Shenzhen, China, People's Republic of, Jiayin Liu

Double auctions, where multiple buyers and sellers bid simultaneously, present unique challenges due to incomplete information, complex interactions among traders and the third-party auctioneer platform. While significant progress has been made in the design of single-sided or multi-item auctions, the optimal mechanism design for double auctions remains an open problem. In this paper, we explore the use of deep learning methods to approximate optimal double auction mechanisms in a general theoretical framework. We first identify three key issues for DL-based methods to auction design: scalability to varying market sizes, inefficiencies in enforcing incentive compatibility (IC) and individual rationality (IR), and instability during the training process. To address these issues, we then propose a transformer-based architecture that models market participants as sequences, enabling flexibility across different market sizes. We reformulate and relax the IC and IR constraints into a tractable form and propose a gradient conflict elimination strategy to enhance constraint enforcement during training. Experimental results show that our approach significantly outperforms traditional analytical mechanisms as well as existing deep learning methods designed for simpler auction settings.

4 - Sharing AI Technologies with Third-Party Developers: Instant, Delayed, OR Not?

Yifan Liu, Tianjin University, Tianjin, China, People's Republic of, Jianqing Chen, Minqiang Li, Haiyang Feng

The rapid advancement of Artificial Intelligence (AI) and the increasing availability of data have motivated software platforms to integrate AI technologies into their first-party applications (apps). While platforms earn commission revenue from third-party developers, the competition between first-party and third-party apps creates a strategic dilemma: should the platform share its AI technology with third-party developers, and if so, share it instantly or with a delay? We develop a two-period game-theoretical model in which a platform, offering an AI-powered first-party app that competes with a third-party app, chooses among three strategies: Instant Sharing, Delayed Sharing, and No Sharing. Special attention is paid to data network effects, a distinguishing feature of AI technologies, implying that the quality of AI grows with accumulated user data. We find that although the Delayed Sharing strategy leads to the lowest AI quality in the second period, it can be optimal by mitigating price competition and preserving the first-party app's competitive advantage in the first period, especially when the AI transfer rate is high and the initial AI quality is moderate. Conversely, the Instant Sharing strategy, despite diminishing the first-party app's technological exclusivity, softens price competition in the first period and achieves the highest AI quality in the second period, making it optimal when both the AI transfer rate and the initial AI quality are low. A stronger data network effect has nonmonotonic impacts on the optimality of these strategies: it increases (decreases) the platform's incentive to retain AI when the initial AI quality is high (low).

5 - Impacts of Knowledge-Sharing Communities on Nonprofessional Hosts in Sharing Economy

jiana meng, Iowa State University, Ames, IA, United States, Chen Zhang, He Li

Online communities around sharing economy platforms have emerged as a new type of online community. Gig workers who provide services or share assets through digital platforms use these online communities to facilitate knowledge exchange. Although some studies have explored information exchange among sharing economy participants, they primarily focus on third-party forums such as Facebook and Reddit. Research on peer-to-peer knowledge sharing in sharing economy platform-sponsored online communities remains limited. These communities, which are typically integrated into the sharing platform, are designed to support gig workers by providing updates from the platform and more importantly facilitating peer support and improving their engagement. The content is usually moderated by the platform owner. This study explores how peer-to-peer knowledge sharing in the sharing economy platform-sponsored online community influences nonprofessional hosts' strategies, performance, and exit on the platform. We find that increased peer-to-peer knowledge sharing in Airbnb-hosted online communities contributes to lower price differentiation, improved demand, and decreased host exits. Our results also suggest two mediation effects. Peer-to-peer knowledge sharing in these communities increases demands, which in turn decreases host exits whereas such knowledge sharing reduces price differentiation, which increases demands and ultimately reduces host exits.

Building B Level 4 B404

Buyer and Suppliers : Models, Agents and Decision Behavior

Invited Session

Behavioral Operations Management

Chair: Brent Moritz, Penn State University, University Park, PA, 16802, United States

1 - Biases of Humans, of AI, and of Humans with AI

Anton Ovchinnikov, Smith School of Business, Queen's University, Kingston, ON, Canada, Yang Chen, Sam Kirshner, Tracy Jenkin, Meena Andiappan

Our research examines whether individuals change their behavioral biases when interacting with LLMs that may also exhibit biases. We design a novel interactive AI experiment and show that AI biases indeed impact human decision-making and discover a new form of nudging. Importantly, we show that how humans interact with AI matters for decision-making.

2 - Distributional Preferences of Large Language Models in Supply Chains: the Roles of Supplier, Buyer, and Relationship

Jie Ning, Case Western Reserve University, Cleveland, OH, United States, Ye Liu

As generative artificial intelligence (GenAI) that harnesses large language models (LLMs) transform the world, more and more companies start to use GenAI in various supply chain interactions such as contract negotiation. This trend makes it imperative to understand the decision-making traits of LLMs, under different personas (supplier vs buyer), and under different supply chain relationships. It has been widely reported that LLMs are more generous and efficiency-driven than the average human in interpersonal contexts. This research takes a first step in characterizing LLMs' distributional preferences in a pricing context in supply chains. We show that GPT-4o has markedly different preferences in a business-to-business setting than an interpersonal setting. In a supply chain, GPT-4o prices products significantly differently when acting as a supplier or a buyer, being consistently more efficiency-driven as a supplier and more fairness-minded as a buyer. GPT-4o may also have surprising perceptions of typical supply chain relationship descriptions. Our findings provide guidance on the customization and design of GenAI tools for companies that currently use, or plan to use, LLMs in supply chain interactions.

3 - Artificial Agents in Operations Management Experiments

Sam Kirshner, UNSW Business School, Sydney, Australia

Built on large language models (LLMs), silicon samples offer a promising approach for advancing behavioral research by simulating decision-making processes and replicating human decision-making in controlled experiments. This study evaluates LLMs' potential to replicate behavioral hypotheses in operations management (OM) by conducting nine studies from the *Management Science Replication Project*. I develop an accessible framework where GPT-4o agents are assigned roles based on System 1 decision-making and participate in the experiments. Remarkably, the silicon samples replicated the core hypotheses in eight of the nine studies, with treatment effects closely matching the direction and magnitude of human decisions. The natural language explanations generated by GPT agents offer insight into their decision logic, revealing whether observed choices align with the behavioral theories being tested. These findings position silicon samples as a valuable tool for replication research, helping researchers distinguish between sampling limitations and theoretical divergence. More broadly, the results support using silicon samples to scale replication, design interventions, and conduct high-fidelity pretests before lab or field deployment.

4 - Supplier Selection and Capacity Constraints

Brent Moritz, Penn State University, University Park, PA, United States

We investigate optimal and observed sourcing decisions when a buyer faces capacity constraints, and suppliers differ in their reliabilities. We consider two suppliers, where one supplier is more costly yet reliable, and the other supplier is less expensive but unreliable. Analytically, we demonstrate that a firm's capacity constraints should impact their sourcing decisions though sunk costs should not impact the decision. Capacity constraints generally favor sourcing more inventory from the reliable supplier. We evaluate these findings in a behavioral experiment. In contrast to theoretical and optimal predictions, when capacity is constrained, we observe that decision makers tend to source more from the unreliable supplier. Similarly, when sunk costs are high, decision makers sourced more from the reliable supplier.

5 - Examining the Effect of Supply Chain CSR Performance and Price Factors on Consumers' Purchasing Decisions

Tim Kraft, North Carolina State University, Raleigh, NC, United States, Junhao Yu, Rob Handfield, Rejaul Hasan, Marguerite Moore

We examine consumers' evaluations of a retailer's communication of its manufacturer's CSR performance (both positive and less than perfect). Using an online shopping context, we conduct both a non-incentivized study and an incentivized study. In both studies, participants were presented with a purchase scenario featuring an apparel item with a CSR performance label and answered questions assessing their purchase intentions. In the incentivized study, a participant's purchase decision influenced the composition of a prize package they could receive (which may include a T-shirt depending on their decision). First, we assess whether communicating CSR performance impacts consumers' purchase intentions. Second, we explore potential mediation paths of this effect in order to illustrate the mechanisms (price fairness and product desirability) by which CSR communication impacts consumers' purchase intentions. Finally, we examine how two price dimensions, retail price and historical price paid, moderate these mediation effects.

We find evidence of our hypothesized indirect effects at the aggregate level under different CSR performance levels, with price fairness being a particularly robust mediator across multiple CSR performance levels. Our moderated mediation study further reveals that the strength of the indirect effects via price fairness varies with consumers' historical price paid and retail price. Specifically, historical price paid moderates the impact of CSR performance on price fairness, with positive (negative) indirect effects evident for consumers with a relatively lower (higher) historical price paid. Conversely, retail price moderates the ancillary impact of price fairness on product desirability, amplifying the moderation effect of historical price paid.

Adaptive experimentation and LLM in Business

Invited Session

Artificial Intelligence

Chair: Wenjia Ba, University of British Columbia, Vancouver, BC, Canada

Co-Chair: Zikun Ye, University of Washington, Seattle, WA, United States

1 - Understanding the Impact of Sampling Quality in Direct Preference Optimization

Yumo Bai, University of North Carolina-Chapel Hill, Chapel Hill, NC, United States

We study the role of the sampling distribution in Direct Preference Optimization 2 (DPO) and aim to understand its impact on DPO's training dynamics. Our analyses 3 show that both the solution space and the convergence behavior of DPO depend 4 on the support and quality of the generating distribution. We first analyze how 5 distribution of responses influences policy updates during gradient descent, drawing 6 connections to common phenomena found in practice. We then design a simplified 7 yet well-structured alignment model as a proxy, and develop quantitative results 8 showing how more frequent high-quality responses amplify the gradient signal 9 and improve the optimization landscape, leading to more effective policy learning. 10 Our theoretical findings are supported by empirical experiments and provide a 11 principled justification for the online DPO framework in practice.

2 - Orlm: a Customizable Framework in Training Large Models for Automated Optimization Modeling

Chenyu Huang, Shanghai University of Finance and Economics, Shanghai, China, People's Republic of, Zhengyang Tang, Shixi Hu, Ruoqing Jiang, Xin Zheng, DongDong Ge, Benyou Wang, Zizhuo Wang

Optimization modeling plays a critical role in the application of Operations Research (OR) tools to address real-world problems, yet they pose challenges and require extensive expertise from OR experts. With the advent of large language models (LLMs), new opportunities have emerged to streamline and automate such task. However, current research predominantly relies on closed-source LLMs such as GPT-4, along with extensive prompt engineering techniques. This reliance stems from the scarcity of high-quality training datasets for optimization modeling, resulting in elevated costs, prolonged processing times, and privacy concerns. To address these challenges, our work is the first to propose a viable path for training open-source LLMs that are capable of optimization modeling and developing solver codes, eventually leading to a superior ability for automating optimization modeling and solving. Particularly, we design the *OR-Instruct*, a semi-automated data synthesis framework for optimization modeling that enables customizable enhancements for specific scenarios or model types. This work also introduces IndustryOR, the first industrial benchmark for evaluating LLMs in solving practical OR problems. We train several 7B-scale open-source LLMs using synthesized data (dubbed ORLMs), which exhibit significantly enhanced optimization modeling capabilities, achieving competitive performance across the NL4OPT, MAMO, and IndustryOR benchmarks. Additionally, our experiments highlight the potential of scaling law and reinforcement learning to further enhance the performance of ORLMs. The workflows and human-machine interaction paradigms of ORLMs in practical industrial applications are also discussed in the paper.

3 - Document Valuation in LLM Summaries: a Cluster Shapley Approach

Zikun Ye, University of Washington, Seattle, WA, United States, Hema Yoganarasimhan

Large Language Models (LLMs) combined with the Retrieval-Augmented Generation (RAG) framework are transforming consumer search and information consumption. Consumers increasingly rely on LLM-based summaries (generated from multiple source documents in response to search queries) instead of reading individual documents/sources. While this simplifies the search and information retrieval process, there exists no established method to quantify the contribution of each document to the overall quality of the LLM-summary, and compensate document creators. In this paper, we first propose a theoretical solution to this problem based on the Shapley value framework that is fair and transparent. While this framework is theoretically appealing, it is practically infeasible since the computational costs of calculating Shapley values grow exponentially with the number of documents. We therefore develop a novel Cluster Shapley algorithm, that leverages embedding-based semantic similarity to cluster similar documents, thereby reducing the number of LLM summarizations and evaluations while maintaining high attribution accuracy. Our approach is particularly well-suited to LLM settings since LLMs themselves can be used to obtain high-quality text embeddings. We apply our approach to a large dataset consisting of Amazon reviews, where LLMs are used to summarize review content. Using a series of numerical experiments, we show that our algorithm achieves up to a 40% reduction in computation time compared to exact Shapley values, and outperforms other baseline approximations. To our knowledge, this work is the first to propose an economic and computational framework for document value attribution in LLM-summarization systems.

4 - Beyond Automation: Large-Model-Powered Automl Reasoning with Knowledge-Driven Insights (Lark) in Marketing Analytics

Lin Lei, University of Maryland, Robert H. Smith School of Business, College Park, MD, United States, Chenyu Huang, Wenzhe Mao, Dongdong Ge, P. K. Kannan

Marketing organizations often struggle with knowledge retention and consistent decision-making due to rapid employee turnover, shifting markets, and complex analytical demands. This study introduces LARK (Large-Model-Powered AutoML Reasoning with Knowledge-Driven Insights), an AI-based approach specifically designed to enhance marketing analytics effectiveness. LARK integrates AutoML and LLMs to iteratively generate contextually meaningful features for time-series prediction or panel regression tasks, with the access to historical information from similar tasks (from organizational memory). LARK efficiently captures and applies insights from historical marketing analytics projects, significantly improving predictive accuracy, reducing analytical redundancy, and supporting agile strategic decisions. We use sales prediction of Chow Tai Fook, a jewelry brand as the empirical validation to confirm LARK's ability. We also apply the manufacturing regression task of FastPrint, a PCB company, to justify the robust performance of LARK even with limited prior knowledge. Additionally, we put together six different empirical analysis and utilize four

different LLMs to highlight LARK's potential to provide enduring competitive advantages through enhanced organizational memory and analytics agility for marketing teams, especially compared to human experts and standard open-source end-to-end LLMs (TimeGPT, TSFM, etc.)

5 - Online Conditional Value-at-Risk Control

Catherine Chen, Stanford University, Stanford, CA, United States, Lihua Lei

We present a generalization of conformal tail risk control to the Conditional Value-at-Risk (CVaR) in an online setting, enabling principled risk-sensitive prediction for a broad class of black-box learning and generative models. Our approach is designed for non-stationary online settings, where the data distribution may drift over time or even shift adversarially, posing significant challenges for traditional risk control techniques. By drawing on deep connections between conformal tail risk control, adversarial online learning, and the variational representation of CVaR introduced by Rockafellar and Uryasev, we develop a novel framework for online CVaR control. This procedure operates model-agnostically, making it broadly applicable in practice. We validate the performance of our method on a range of real-world datasets, including high-stakes financial forecasting tasks and large language models (LLMs), where tail risks can be particularly costly. Our experiments demonstrate the consistency of our proposed algorithm for maintaining desired risk levels dynamically.

Critical Thinking in the Age of ChatGPT: Insights from Teaching, Trials, and Tools

Invited Session

INFORMS Committee on Teaching and Learning

Co-Chair: Gabriela Gongora-Svartzman, Khoury College, Northeastern University, Miami, FL, United States

1 - Student AI Usage in Higher Education

Daniel Nielubowicz, University of Washington, Bothell, WA, United States

This study investigates the utilization of AI tools by students in higher education, examining usage trends, academic impact, and ethical considerations. It identifies challenges such as digital literacy gaps and access disparities, providing valuable insights for institutions to foster responsible and effective AI integration in academic settings.

2 - The Impact of Generative AI on Student Success: Evidence from a Randomized Controlled Trial in Business Education

Insung Hwang, Columbus State University, Columbus, GA, United States, John Finley

This randomized controlled trial investigates the impact of generative artificial intelligence (AI) tools on student academic success in higher education. The study involves 30 classes across multiple disciplines at a public university, randomly assigned to either an intervention group with structured access to a generative AI assistant (e.g., ChatGPT) or a control group with AI prohibition policies and measures. Over a semester, the intervention group is allowed to use the AI tool for assignments including idea generation, essay drafting, and coding support, with training on ethical and effective use. Key outcomes of the investigation include course grades, assignment quality, student retention in the current and next semester, and the students' job-market-related metrics such as internship placement, interview invitations, and job placement. In addition to estimating the causal effects of generative AI on academic and career-related metrics, the study also explores the boundary conditions across contextual factors and individual factors—such as disciplinary type, course type, instructor approach, and student characteristics (previous academic history/demographic factors)—that moderate the effectiveness of AI integration. This study provides early causal evidence on whether and when generative AI tools can enhance student performance and engagement in academic settings. The findings aim to inform the pedagogical potential of AI and support the development of evidence-based policies and guidelines for its integration in educational settings.

3 - Improving Student's Critical Thinking Skills Using ChatGPT Generated Essays

Zoe Long, University of Florida, Gainesville, FL, United States, Elif Akcali

With the increasing growth of large language models use in higher education, it is increasingly important that students understand the limitations of these tools. To better understand students' current opinions and how they may be affected by being exposed to mistakes made by ChatGPT, we designed this research study. We provided undergraduate industrial and systems engineering students in a supply chain course with an assignment to ask ChatGPT to generate two different essays about two different supply chain topics previously discussed in the course. Students were then asked to identify factual and logical errors within these essays along with incorrect or incomplete citations. Students completed pre- and post-surveys using 5-point Likert scales assessing their agreement with statements about ChatGPT's use in education (1=strongly disagree, 5=strongly agree) and its perceived helpfulness for specific tasks (1=completely unhelpful, 5=extremely helpful). 38 of the 55 students in the course consented to having their data included in this study. We compared the results of the pre- and post-surveys to assess changes in student opinions of ChatGPT. We also investigated whether the number and type of mistakes identified by the students relate to the changes in their opinions. This research will examine what changes were found in students' opinions after being exposed to mistakes made by ChatGPT.

4 - Harnessing the Power of Learning Analytics for Metacognition Skills Development

Anita Lee-Post, University of Kentucky, Lexington, KY, United States, Kun Huang

Metacognition skills are essential for individuals to take control of their learning and thinking, enabling them to achieve both professional and personal goals. When powered by learning analytics, individuals can enhance their metacognitive abilities based on reliable evidence and insights gleaned from data collected about their learning and thinking processes as they interact with the learning management systems to complete learning tasks and activities. In this talk, we will present a research study designed to improve students' academic performance with the use of learning support exercises for the four phases of metacognition: planning, monitoring, evaluation, and reflection. The learning support exercises are labeled as study plan set up, study plan follow up, study plan tune up, and study plan wrap up to represent each of the four phases of metacognition respectively. All exercises involve helping learners align their learning goals with a solid study plan. Results from implementing the research study in an undergraduate Business Analytics online class are discussed.

Data-Enabled Analytics: Integrating Efficiency, Intelligence, and Impact

Invited Session

Data Mining

Chair: Dariush Khezrimotlagh, Pennsylvania State University - Harrisburg, Middletown, PA, 17057, United States

Co-Chair: leili Soltanisehat, University of Massachusetts Dartmouth, North Dartmouth, MA, United States

1 - Beyond the Frontier: Learning from Observed Units in Multi-Stage System Performance Analysis

Dariush Khezrimotlagh, Pennsylvania State University - Harrisburg, Middletown, PA, United States, Yao Chen

This study introduces a practical method for evaluating multi-stage business processes using observed data. Unlike traditional models that rely on hypothetical scenarios, our approach ensures transparency and realistic benchmarking. It empowers decision-makers with reliable insights to assess efficiency, optimize operations, and support data-driven performance improvements.

2 - Enhancing Deep Learning with Data Envelopment Analysis: Market-Aware Recommendation System for Non-Fungible Tokens

Kexin Lin, Worcester Polytechnic Institute, Worcester, MA, United States, Joe Zhu

Non-Fungible Tokens (NFTs), unique digital assets authenticated via blockchain, have emerged as transformative instruments for representing ownership across diverse sectors such as art, gaming, and decentralized finance. The rapid expansion of NFT market, however, brings critical challenges in establishing NFT recommendation

systems that have the ability to reconcile artistic appeal with financial value, extract insight from sparse and noisy interaction data, and match individual preferences to market performance. To tackle these challenges and help users to decide which NFT to buy, we develop a purchase-oriented Transformer Network-based recommendation system that first uses data envelopment analysis (DEA) to assess how NFTs convert intrinsic characteristics into market success. DEA generates market performance scores and establishes reference relationships among NFTs. Using DEA scores with NFTs' intrinsic attributes, we construct three complementary graphs to capture multifaceted relationships: a directed DEA-reference graph that links each NFT to its benchmarks, an undirected performance-cluster graph that connects NFTs in the same performance cluster, and an undirected trait-similarity graph linking NFTs sharing similar traits. A temporal Transformer leverages these relation-specific graphs and DEA scores to recommend NFTs for each user to purchase that simultaneously align with user preferences and exhibit strong market performance. Applications on CryptoPunks dataset demonstrate that our proposed DEA-enhanced Transformer Network (DETN) recommendation system achieves higher accuracy than state-of-the-art baseline models such as collaborative filtering, graph-based methods, and Transformer-based models. By integrating DEA with deep learning method, DETN enhances recommendation precision and supports better informed decision-making processes.

3 - Unified Modeling of Sequential and Cross-Modal Dependencies via Adaptive Multimodal Deep Architectures

Yeganeh Abodollahinejad, Pennsylvania State University, Harrisburg, PA, United States, Dariush Khezrimotlagh

Deep learning systems deployed in real-world settings must often interpret data that is both multimodal and temporally structured. A modular and adaptive architecture is introduced to unify the modeling of sequential and cross-modal dependencies within a single deep learning framework. By combining attention-based temporal reasoning with dynamic cross-modal fusion, the model captures both time-evolving signals and interactions among heterogeneous data sources. Unlike traditional pipelines that treat modalities or time separately, this approach enables unified representation learning, enhancing generalization and reducing reliance on task-specific tuning. The system dynamically adapts to missing data, shifts in modality quality, and variability in sequences through gated components and learnable weighting mechanisms. Multi-objective optimization is employed to jointly balance prediction accuracy, modality confidence, and temporal consistency. Interpretability is supported through modular design and attention-based mechanisms, enabling traceable information flow across inputs and components. The system is designed to remain robust under noisy, imbalanced, and dynamic data conditions. By integrating multiple learning objectives into a cohesive framework, the system provides a principled solution to the challenges of multimodal, sequential inference. Its design supports both rigorous modeling and practical, real-world utility.

4 - A Data-Driven Analysis of ESG Impacts on Financial Performance Across Industries and Regions

leili Soltanisehat, University of Massachusetts Dartmouth, North Dartmouth, MA, United States

This study examines how firms' financial performance is influenced by Environmental, Social, and Governance (ESG) practices, with an emphasis on the moderating roles of industry characteristics and regional contexts. While prior research often focuses on company-level factors, this study addresses the gap by integrating firm- industry- and region-specific dimensions. To capture complex and context-dependent relationships, the analysis applies data-driven models, including various machine learning techniques, enabling nuanced assessments of ESG impacts across sectors and regions. The findings reveal significant heterogeneity in ESG's financial effects, offering actionable insights for investors and managers to adopt tailored ESG strategies aligned with industry dynamics and regional institutional settings.

Advances in Trustworthy Machine Learning: Interpretability, Fairness, and Intelligent Control in Healthcare and Beyond

Invited Session

Data Mining

Chair: Rachel Bennett, University of Oklahoma, Oklahoma City, OK, United States

1 - Robust Outcome Optimization Through Multi-Model Inverse Classification

Shun Dong, University of Kansas, Lawrence, KS, United States, Michael Lash, Qihang Lin, Nick Street

Predictive models have become central to modern decision-making across a wide range of domains, including finance, healthcare, and manufacturing. While these models excel at forecasting future outcomes, they often fall short in offering actionable guidance. Inverse classification, a key technique within the broader framework of algorithmic recourse, addresses this limitation by generating prescriptive recommendations alongside predictions. In this work, we introduce a multi-model inverse classification framework that leverages a novel proximal linear algorithm designed to solve difference-of-weakly-convex optimization problems. Our method enables decision-makers to steer outcomes toward desirable targets while explicitly accounting for a defined level of "risk." We evaluate the proposed framework on real-world datasets, and the empirical results demonstrate its effectiveness and robustness in generating outcome-optimizing prescriptions, thereby validating its practical applicability.

2 - Smarter Cells, Smarter Control: Reinforcement Learning for Fermentation Optimization

Airi Shimamura, University of Oklahoma, Norman, OK, United States, Farid Talebnia Rowshan, M. Soheil Hemmati, Talayeh Razzaghi

Optimizing bioprocesses is a key challenge in biomanufacturing, with fermentation playing a pivotal role in determining both productivity and profitability. However, the inherent complexity of cellular mechanisms poses significant challenges for developing accurate mechanistic models that capture these dynamics. Traditional optimization approaches often rely on extensive experimental datasets, making them costly and time-consuming. To address these limitations, we propose a reinforcement learning (RL) framework that formulates the bioprocess as a sequential decision-making problem. RL is particularly well-suited for this application, as it learns optimal control policies through iterative interaction with the environment, without requiring explicit system models. The proposed RL-based control strategy is designed to optimize fermentation conditions by maximizing protein production while minimizing impurity accumulation and operational expenditures. The results demonstrate the potential of RL as a data-efficient, adaptive optimization tool for complex biomanufacturing processes.

3 - Decision Support Systems for Health Practitioners: An Interpretable Deep Learning Framework to Navigate Diagnostic Uncertainty

Maryam Kheirandish, Emory University, Atlanta, GA, United States, Shengfan Zhang, Ryan Suk

Health systems are currently facing unprecedented financial challenges, exacerbated by the suboptimal utilization of diagnostic tests. Both the overuse and underuse of these tests deplete essential health resources and impede timely diagnosis and effective treatment. A primary driver of test overuse is the inherent uncertainty in medical decision-making; merely ordering additional diagnostic tests does not guarantee the prevention of missed conditions. To counteract this, we propose an interpretable deep learning framework designed to assist physicians by providing clear insights into a patient's current health status, leveraging existing test results and associated uncertainties. This empowers physicians to make informed decisions regarding the necessity of additional tests or the feasibility of proceeding with treatment based on available data, thereby ensuring conditions are not overlooked. While predictive uncertainty may suffice for decision-making at the diagnosis stage, ongoing treatment monitoring necessitates a more dynamic, sequential decision-making approach. In this study, we introduce an interpretable deep learning framework that integrates uncertainty quantification within outcome prediction models to significantly improve treatment monitoring strategies. This framework is specifically designed to identify scenarios where additional monitoring tests can enhance the predictive certainty of treatment outcomes. The model considers the immediate impact of test ordering on current predictive uncertainty, as well as its influence on subsequent predictions used in future patient follow-ups. We demonstrate the practical utility and efficacy of this model through its application to enhance the treatment monitoring of tuberculosis patients.

4 - Improving Maternal Health: Predicting Length of Stay in Preeclampsia with Imbalanced Learning

Talayeh Razzaghi, University of Oklahoma, Norman, OK, United States, Leama Tah, Rachel Bennett, Mulla D Zuber

Hypertensive disorders during pregnancy, including preeclampsia, are among the leading causes of maternal and neonatal morbidity and mortality. Preeclampsia affects approximately 2-8% of pregnancies in the United States, with a disproportionately higher incidence among African American women (6.04%) compared to Caucasian women (3.75%). The condition often requires intensive care unit (ICU) admission, leading to prolonged hospital stays and increased healthcare burdens. This study aims to predict the length of stay for preeclamptic patients using supervised machine learning techniques applied to an imbalanced healthcare dataset. We exploit and compare several approaches to address imbalanced data to improve predictive performance and model trustworthiness.

5 - Survival Analysis for Risk Stratification of Clinical Events in Heart Failure Patients Using Longitudinal EHR Data

Maryam Jafaripakzad, University of South Florida, Tampa, FL, United States, Jorge Acuna, Jose Zayas Castro, Joel Fernandez

Heart failure is a chronic condition associated with frequent hospitalizations and a high risk of adverse clinical events, posing significant challenges to both patients and healthcare systems. Using time-dependent data collected in real-world clinical settings can improve our ability to anticipate patient deterioration and guide timely interventions. In this study, we develop a deep learning framework that utilizes longitudinal electronic health record data extracted from the EPIC system to model patient trajectories and predict critical clinical events in the months ahead. We propose a hybrid model combining a Temporal Convolutional Network (TCN) with an autoencoder to capture the temporal dynamics and latent characteristics of individual patients. The autoencoder component extracts compact, informative representations of multivariate patient data, while the TCN captures sequential patterns over time. This model enables survival analysis of multiple adverse events such as cardiogenic shock, transplant, LVAD implantation, and mortality. Our dataset includes a diverse cohort of heart failure patients with varying numbers of hospital or clinical encounters, irregular visit intervals, and heterogeneous clinical measurements which reflect the complexity of our dataset. The model is trained to predict the risk of each event in the upcoming months which offers a personalized risk profile for each patient. This approach not only improves predictive performance but also allows for interpretable patient representations that can support risk stratification and care planning.

Chair: Niyazi Taneri, University of Cambridge, Cambridge, United Kingdom

2 - Improving Farm Productivity and Technology Adoption Through LLM-Powered Digital Advisory: a Randomized Controlled Trial Among 2,000 Smallholder Rice Farmers

Canberk Ucel, ESSEC Business School, Paris, France, Ali Aouad, Alp Sungu, Niyazi Taneri, El Ghali Zerhouni

Low adoption and ineffective implementation of sustainable agricultural technologies continue to undermine productivity and environmental outcomes in smallholder farming systems. This study presents one of the first large-scale randomized controlled trials (RCTs) testing the use of Large Language Model (LLM)-based AI advisory bots to address these challenges. We examine whether delivering personalized, on-demand guidance via common messaging platforms on farmers' smartphones can improve farm management practices and the adoption of Direct-Seeded Rice (DSR) technology—a practice with demonstrated environmental and economic benefits. Our ongoing experiment targets 2,000 smallholder rice farmers across four major rice-growing regions in the Philippines. Participants are randomly assigned to a control group or one of two treatment arms: access to an AI advisor bot, or access with additional incentives designed to encourage initial engagement. The advisory bot integrates technical content from Bayer CropScience and public sources and is tailored to local farming contexts. We collect detailed survey and interaction data throughout the growing season and apply econometric and qualitative methods to evaluate technology adoption, farmer engagement, productivity, and AI-human interaction patterns. The study advances research at the intersection of agricultural development, operations management, and AI deployment in low-resource environments. It offers practical insights into the design of scalable digital advisory systems and the behavioral dynamics underpinning sustained technology use. Findings will inform policy and industry efforts aimed at improving agricultural productivity, climate resilience, and the cost-effectiveness of extension services in developing countries.

3 - Incentivizing Project Managers Competing for R&D Funds

Niyazi Taneri, University of Cambridge, Cambridge, United Kingdom, Ozge Tuncel, Nektarios Oraopoulos, Jochen Schlapp

Theory suggests combining shared and individual incentives can align the incentives of managers competing for R&D funds. We characterize the optimal contract that incentivizes project managers to evaluate their projects and truthfully report evaluation outcomes, which determines the firm's resource allocation decision. Through a series of treatments, we then explore the contract's interaction with different business environments. Our experimental results indicate that the optimal contract alone doesn't sufficiently motivate project managers, suggesting that the business environment, paired with the optimal contract, plays a crucial role in moving toward theoretical outcomes.

4 - Do Workers and Customers Benefit from Competition Between on-Demand Service Platforms

Sangyoon Cha, University of Michigan Ann Arbor, Ann Arbor, MI, United States, Saif Benjaafar, Shihong Xiao, Xiaotang Yang

We study competition between two on-demand service platforms: an incumbent and a new entrant. The platforms compete for both workers and customers, deciding on wages to pay workers and prices to charge customers. Workers, who are heterogeneous in their opportunity costs, are sensitive to both the wage and utilization. Customers, who are heterogeneous in their preferences for the platforms, are sensitive to both the price and delay. We show that there are cases where both workers and customers are worse off after the new platform enters the market (with workers being busier but earning less, and customers paying more but experiencing more delay). Moreover, prohibiting workers from multihoming (i.e., working for both platforms) can flip the outcomes for workers (they become less busy but earn more) while customers continue to be worse off (they pay more).

1 - At the Intersection of AI, Data, and Advanced Materials and Manufacturing

Changchun Zeng, Florida State University, Tallahassee, FL, United States

This presentation overviews the diverse research in the Department of Industrial and Manufacturing Engineering (IME). We have an outstanding group of faculty members working in the areas vital to the national interest and to the betterment of society, i.e., advanced materials and manufacturing, nanomaterials and nanotechnology, smart materials, data science and analytics, artificial intelligence, machine learning and deep learning, systems engineering, transportation systems and supply chain logistics. Our faculty members are involved in these exciting areas on projects sponsored by prestigious funding agencies, i.e., NSF, NIH, DOE, DOD, NASA, AFRL, ONR, to name a few.

2 - Optimization Solution Development and Deployment: a Framework for Success

Irv Lustig, Princeton Consultants, Coral Gables, FL, United States

For over 44 years, Princeton Consultants has developed and deployed numerous applications that leverage optimization to make better decisions for our clients. We have developed a set of best practices over that time that are also reflected in the recently published INFORMS Analytics Framework (IAF), for which Irv was a key contributor. The IAF provides a roadmap for successful analytics projects, including optimization, and contains specific tasks related to risk management. Irv will describe

both the IAF and the Princeton 20, a set of 10 environmental and 10 technical risks to be evaluated at the commencement of any project. Understanding these risks in the context of the framework leads to best practices that improve the chances of success for your next optimization project.

1 - Inform's Prize-Micron

Sanjay Dasam, Micron Technology, Eagle, ID, United States, Shiva Esturi

Micron Technology, a global leader in memory and storage solutions, is dedicated to transforming the way the world uses information to enrich life for all. Founded in 1978 in Boise, Idaho, Micron has grown to over 50,000 employees worldwide, generating \$25.1 billion in revenue in fiscal year 2024. Micron's industry-leading technologies enable the world around us – from cutting edge artificial intelligence solutions to automotive, Industrial IoT, mobile, and personal computing. At Micron, we leverage a variety of operations research (O.R.) and analytics applications to optimize our operations and decision-making processes. Our initiatives have significantly improved planning, procurement, manufacturing, and logistics and fulfillment. For instance, Micron's use of hierarchical linear programming to optimize supply planning has improved supply-constrained demand satisfaction by 4%, reduced over \$50M in working capital, and recurring manufacturing cost reduction of more than %15M. Micron Master Production Scheduler enhances production schedules for our Wafer Fabrication using advanced analytics. This tool has achieved a wafer fabrication throughput increase of 0.5%, equivalent to \$288 million. Additionally, our Capacity Planning Optimization solution uses a combination of mathematical and simulation techniques to generate optimal capacity plans, helping Micron save more than \$100 million every year. Micron's innovative use of O.R., data science, machine learning, and analytics has not only enhanced our operational efficiency but also positioned us as a leader in the semiconductor industry. We are proud to share our journey and achievements with the INFORMS community.

1 - Charting the Unseen: Uncovering the Dynamic Processes Underlying Human-Genai Interaction in Complex Problem Solving

Ziyi Zhao, Temple University, Philadelphia, PA, United States, Kanghyun Cho, Aleks Aaltonen

Generative artificial intelligence (GenAI) is reshaping the landscape of work by redefining how professionals solve complex problems, moving beyond traditional search methods to generate innovative and context-specific solutions. This transformative shift has a profound impact on job roles, responsibilities, and the skills required for effective human-AI collaboration. IT professionals face the critical task of navigating these changes, balancing the potential productivity and innovation gains of GenAI adoption with the need to manage technological risks and ethical considerations. This study directly addresses how IT professionals evaluate and use GenAI-generated solutions in complex problem-solving tasks. Specifically, this research introduces Screen Tracking of Research Engagement, an innovative methodology that employs continuous video-based monitoring of participant interactions within the research environment. By capturing detailed clickstreams, navigation paths, and interaction patterns, this method provides rich contextual insights into participants' cognitive processes and decision-making strategies. The analysis of thousands of minutes of videos of dynamic interactions of GenAI illustrates different strategies that professionals employ when interacting with GenAI. As a result, this research underscores the importance of cultivating prompt representation technique that enables professionals to iteratively guide GenAI toward accurate and contextually tailored outputs.

2 - From Error to Inspiration: Exploring the Impact of AI Hallucination on Creativity

Fanshu Li, George Mason University, Fairfax, VA, United States, SIDDHARTH BHATTACHARYA, Bowen Lou

Abstract

As AI tools like large language models (LLMs) become more embedded in creative work, it is important to understand how they affect human idea generation. One of the most intriguing aspects of these LLMs is their tendency to produce hallucinated content. While such content can mislead or confuse users, it can also prompt unexpected connections and spark original ideas. This study explores the complex role of AI hallucination in shaping human creativity. Rather than treating inaccuracies as purely negative, we examine how different levels of hallucination may hinder or enhance divergent thinking. Theoretically, this research contributes to creativity studies by introducing the idea that hallucinations can inspire novel thinking, challenging the traditional assumption that errors only interfere with performance. It also adds to human-AI interaction research by showing how users engage with imperfect systems during open-ended tasks. Practically, the findings offer guidance for designing AI tools that better support creativity. By identifying conditions under which hallucinations are helpful or harmful, developers and users can adjust system settings and workflows to make the most of AI assistance. These insights are especially relevant for creative industries, education, and ethical AI deployment.

3 - The Double-Edged Sword of AI Assistants in Customer Service: Balancing Efficiency and Human Skill Retention

Shizhen Jia, Quinnipiac University, Hamden, CT, United States, Guohou Shan

The increasing adoption of artificial intelligence (AI) assistants in customer service has transformed how organizations manage customer interactions, offering benefits such as enhanced efficiency, cost reduction, and improved response times. However, as AI systems take on routine tasks, concerns arise regarding their long-term impact on human employees' skills, job satisfaction, and autonomy. While existing research has explored AI's role in augmenting human capabilities and improving customer satisfaction, little attention has been paid to the risks of overreliance on these technologies.

This study addresses this gap by conducting a longitudinal field experiment in a large company's customer service department. Three hundred representatives are randomly assigned to an AI-assisted group or a control group using traditional methods. Over six months, performance metrics—including response time, resolution rates, and customer satisfaction—are tracked alongside employee problem-solving skills, job satisfaction, and autonomy. The study also introduces an intervention, incorporating "AI-free" days and gamified challenges to mitigate potential skill erosion and promote active engagement.

By examining the trade-offs between AI-driven efficiency gains and the long-term implications for human workers, this research provides empirical insights into the evolving role of AI in customer service. Findings will contribute to the discourse on responsible AI adoption and inform strategies for balancing technological advancement with human skill development.

4 - AI's Job Shakeup: Analyzing the Uneven Impact of Ai Adoption on Labor Demand

Xiupeng Wang, Northeastern University, Boston, MA, United States, Bin Gu, Mohammad Soltanieh-ha

This research investigates the influence of Artificial Intelligence (AI) adoption on labor demand within publicly traded enterprises. We develop A novel metric of AI adoption, derived from the analysis of 10-K filings, and AI activities are classified into three distinct categories: "Ops" (operational use), "Dev" (AI development), and

“None.” This classification is conducted using an unsupervised methodology leveraging OpenAI’s GPT-4o model, guided by predefined category prompts and is trained with sentence transformer “all-MiniLM-L6-v2” model. Utilizing AI exposure measures at the occupational level from Webb (2019), findings indicate a negative correlation between AI adoption and job postings in occupations with high impact across the entire sample, whereas no significant correlation is observed with low impacted occupations. Heterogeneity analyses reveal that these effects are predominantly attributed to non-IT service sectors and firms lacking internal AI technology development. This study demonstrates the uneven association of AI with labor demand, highlighting disparate levels of disruption across specific occupations and industries.

5 - Generative AI May be Good for Artists: Understanding the Impact of Artistic Style on Preference and Willingness to Pay

J. Bell, Penn State University, Phoenix, AZ, United States, Wen Wang, Jeffrey Dotson, David Schweidel

Generative AI tools, such as MidJourney, Stable Diffusion, and DALL-E, allow users to generate high-quality images using simple text prompts and have seen wide adoption.

However, the ability of these tools to mimic the styles of specific artists has raised ethical and economic concerns. Artists argue that their intellectual property is being exploited without consent or compensation, fueling calls for fair remuneration. In this paper, we propose a constructive alternative: generative AI as a means for artists to monetize their unique styles, transforming a perceived threat into an economic opportunity. Using a multi-method approach, including large-scale prompt analysis, deep learning models, and conjoint choice experiments, we demonstrate that artist styles can enhance image quality, increase consumer preference, and drive higher willingness to pay (WTP) even under conditions of incentive alignment. Importantly, consumers express strong support for fair compensation schemes, creating a viable pathway for artists to participate meaningfully in the generative AI ecosystem. These findings have implications for technology developers, artists, and policymakers seeking to balance innovation with fairness.

1 - Hybrid Hidden Markov Models for Modeling Equity Return Dynamics

Abdulrahman Alswaidan, Cornell University, Ithaca, NY, United States, Jeffery Varner

This talk introduces a hybrid probabilistic framework for modeling equity returns, designed to capture empirical phenomena such as heavy tails, volatility clustering, and regime-switching behavior commonly observed in financial markets. Standard models, such as geometric Brownian motion, rely on assumptions of normality and constant volatility, which often fail to reflect the complex dynamics of real-world asset returns. Our approach integrates discrete-state Hidden Markov Models (HMMs) with a Poisson jump component, enabling the simulation of both persistent market regimes and abrupt return shocks. Each hidden state represents a distinct market condition, ranging from severely bearish to strongly bullish with transitions governed by empirically estimated Markov chains. The Poisson process captures rare but significant return jumps, enhancing the model’s ability to replicate observed return distributions. We validate the framework using a dataset of over 400 U.S.-listed equities and exchange-traded funds (ETFs) spanning 2,515 trading days, incorporating open-high-low-close (OHLC) prices, trading volume, and volume-weighted average price (VWAP) data. Simulations on assets such as NVDA, AAPL, and SPY successfully reproduce key empirical features, including heavy tailed return distributions, volatility clustering, and the absence of autocorrelation. For instance, Kolmogorov–Smirnov tests show that 98% of in-sample SPY simulations align with historical distributions at the 95% confidence level. Furthermore, out-of-sample evaluation over 277 trading days maintains 84% statistical consistency. These findings underscore the utility of regime-switching models in financial time series analysis, demonstrating how hybrid HMM based approaches can reveal latent market structures and sentiment dynamics under uncertainty.

2 - An Endogenized Controller Design for Speculative Market Dynamics

James Paine, Bucknell University Freeman College of Management, Lewisburg, PA, United States

Speculative bubble formation has been a long observed feature of markets, and continues to be a major focus of economic, marketing, and operations management research. While these bubbles may form because of specific physical or informational features of specific markets, it is also the interplay of current realized prices and future expected rewards, offset by rising risk of loss with increased speculation, that drives their formation. In other words, it can be the behavioral features of individual decision makers more so than the physics of these markets that yield these bubbles. The comparison of a current state of a system with some expected state in terms of instantaneous, forward projected, and cumulative observations is a feature of both this speculative bubble formation and classical control theory as well. This work presents a framework for adding more behaviorally realistic endogeneity into a classical proportional-integral-derivative (PID) controller design and illustrates its use in modeling speculative bubbles that both imbue and destroy value in an underlying commodity. More practically, this framework can be considered as the basis for a new fundamental unit modeling structure that bridges between control theory from operations research and speculative pricing theory from behavioral economics.

3 - Valuation, Weighted Average Cost of Capital, and Cost of Equity Under a Constant Leverage Ratio

Luis Chavez-Bedoya, ESAN Graduate School of Business, Lima, Peru

This study analyzes corporate valuation through the Weighted Average Cost of Capital (WACC) and Adjusted Present Value (APV) methods, assuming constant leverage. It thoroughly examines cost of equity and WACC calculation techniques, specifically investigating how constant (versus variable) discount rates affect investment valuations. The research identifies the cash flow conditions that validate using constant discount rates in financial modeling and develops a framework to properly discount future cash flows while isolating interest tax shield effects. Key contributions include: (1) methodological insights into maintaining fixed discount rates across valuation periods, (2) quantitative analysis of tax shield valuation under constant leverage, and (3) practical guidance for choosing between constant and variable rate approaches. The findings enhance understanding of capital structure effects on valuation accuracy in both WACC and APV contexts.

4 - CapOptix: An Options-Approach Based Framework for Capacity Market Pricing Models

Millend Roy, Columbia University, New York, NY, United States, Agostino Capponi, Vijay Modi, Vladimir Pyltsov, Yinbo Hu

Electricity and capacity markets increasingly face challenges in maintaining system reliability amid rising variability, investment uncertainty, and extreme demand-supply events. We present **CapOptix**, a pricing framework that redefines capacity market design through the lens of financial option theory. By modeling capacity commitments as **reliability options**—derivative contracts on wholesale electricity prices—CapOptix derives fair capacity premia under realistic stochastic dynamics, including Brownian motion, Geometric Brownian motion, GARCH models, jump-diffusion processes, and regime-switching frameworks. Departing from traditional mechanisms, CapOptix incorporates **Conditional Value-at-Risk (CVaR)** into its pricing architecture to capture rare but high-impact tail events, addressing risk dimensions that conventional expected-value metrics fail to reflect. The framework aligns incentives with system adequacy by rewarding capacity providers for mitigating extreme shortages rather than merely covering average conditions. A breakeven analysis shows that the derived premia closely approximate the **Net Cost of New Entry (NetCONE)**, while simultaneously identifying minimum contract durations necessary for investment viability.

CapOptix is empirically validated using real-world data from **Germany and NYISO**, two markets with distinct price dynamics. The approach demonstrates strong generalizability across European and U.S. contexts, supported by shortfall-driven price estimation calibrated via regression and evaluated through Monte Carlo simulation.

Overall, CapOptix delivers a robust, risk-sensitive, and flexible pricing mechanism for capacity markets. It offers practical tools for procurement under uncertainty and establishes a foundation for market reforms that can adapt to the evolving challenges of modern power systems.

5 - Greenium in Transition: Media Signals and the Pricing of ESG vs. Emission-Based Sustainability

Ruobing Yan, Harbin Institute of Technology, Harbin, China, People's Republic of, Qiang Ye

As awareness grows around the financial implications of climate change, sustainable investing is undergoing a strategic shift—from broad-based ESG integration to a more targeted focus on climate-specific metrics such as greenhouse gas (GHG) emissions. This research investigates how media signals—across both traditional news and social platforms—influence the pricing of sustainability in capital markets, specifically through the greenium: the differential in stock valuation between green and brown firms. Leveraging firm-level data, we compare greenium patterns when “greenness” is measured by subjective ESG scores versus objective GHG emission metrics. By integrating media sentiment and attention to “climate change” as explanatory variables, we model the informational pathways through which investor climate awareness moderates the relationship between sustainability indicators and market valuation, assessing how media-driven salience shapes investor responses to both perception-based and data-driven indicators of environmental performance. This study sheds light on the evolving dynamics of sustainable investment strategy, demonstrating how media systems condition market recognition of environmental risk and contribute to the strategic transition from ESG-based to climate-focused investing. The research bridges climate finance and information systems by translating sustainability indicators into financial valuations through media analytics, identifying the informational drivers of green asset pricing. Findings of the work would provide insights for investors seeking climate-hedged portfolios, regulators designing disclosure policies, and data providers developing the next generation of sustainability metrics in the post-ESG era.

Well INFORMED PhD Retreat: Reclaiming Wellness in the Academy

Panel Session

Ambassadors Program

Co-Chair: Jessye Talley, Morgan State University, Baltimore, MD, United States

1 - Moderator Panelist

Jessye Talley, Morgan State University, Baltimore, MD, United States

Pursuing a doctorate is often marked by rigorous coursework, unrealistic expectations, and chronic stress—conditions that can push personal well-being to the sidelines. Unfortunately, this culture of self-sacrifice doesn't end at graduation. It often follows scholars into faculty life, where the pressure to publish, teach, and serve continues unchecked.

As part of our WELL INFORMED initiative, we're hosting a mini PhD retreat designed specifically for PhD students and early to mid-career faculty. This experience will include a restorative mix of discussion, reflective activities, and community connection, all aimed at helping you reimagine what wellness, productivity, and success can look like in academic life.

This isn't just about surviving the PhD or tenure track—it's about building a new, healthy, and effective normal within the academy

2 - Panelist

1 - ChatGPT's Impact on Political Discourse: Evidence from Reddit

Xiaoning Wang, University of Texas at Dallas, Richardson, TX, United States

Large language models such as ChatGPT have transformed how people access information and create content. However, there has been little research on how these models affect individuals' political attitudes and expressions. In this paper, we investigate how the release of ChatGPT influenced political discourse on social media platforms. We collect data from the largest political discussion subreddit on Reddit and measure the political slant of each comment to infer each author's dynamic political stance. We find that the release of ChatGPT significantly intensified political polarization among users on the platform: users who were originally liberal-leaning became more liberal-leaning, and vice versa for those who were conservative-leaning. Further analysis reveals that this polarization was primarily driven by less active users who used ChatGPT to generate more extreme comments. Although active users did not appear to use ChatGPT themselves, they also became more active.

Interestingly, we find that ChatGPT did not reduce the level of civility on the platform or increase expressions of anger or disgust; instead, both hostility and toxicity on the platform declined, suggesting that while political polarization increased, affective polarization decreased, indicating that ChatGPT may have improved the quality of online political discourse.

2 - Does Platform Fragmentation Harm Innovation?

Yi Liu, University of Wisconsin-Madison, Madison, WI, United States, Zhuoxin Li

Platform fragmentation refers to the coexistence of multiple versions of a platform technology (e.g., Android 8 vs. Android 9) adopted by the users. The literature has highlighted the negative effect of fragmentation on innovation on the platform under the assumption of homogeneous developers, and found that fragmentation always harm innovation. In this paper, we consider heterogeneous developers, one big developer and one small developer. The big developer has cost advantage over the small one. Our analytical model shows that platform fragmentation is not always harmful. Platform fragmentation On one hand, platform fragmentation hinders complementary innovations by increasing developers' costs of serving multiple market fragments. Higher degree of platform fragmentation leads to less complementary innovations. On the other hand, platform fragmentation causes market segmentation and reduces the winner-take-all propensity. As a result, a higher degree of platform fragmentation is associated with more frequent innovations from small developers, and therefore, greater diversity of complementary innovations. An empirical study of the Firefox platform and its add-on market provides support of the analytical results.

3 - Learning User Engagement Using Deep Matching Embeddings in the Gaming Platform

Kan Xu, Arizona State University, Chandler, AZ, United States, Yu Qin, Olivia Sheng

In the competitive landscape of online gaming platforms, predicting short-term user engagement is critical for retaining users and maintaining platform success. Existing methods that rely on demographic data and gameplay statistics often fail to capture the complexity of user behaviors and interactions, limiting their ability to predict disengagement accurately. To address this, we propose a deep learning framework designed to model the gaming process and provide interpretable insights into why users may disengage. Our approach creates user embeddings by integrating diverse match-specific data, including game outcomes, in-game dialogue, and paralinguistic cues like emojis, to comprehensively capture user experiences. The model incorporates the game structure and user interactions, allowing it to explain potential causes for short-term user dropout. Using a multi-task learning strategy, the framework predicts engagement while considering behavioral and emotional signals, offering a nuanced view of factors influencing user retention. Crucially, our framework balances interpretability and predictive performance. It provides actionable insights that enable platforms to develop targeted retention strategies informed by a deeper understanding of user disengagement. Empirical evaluations using real-world gaming data show that our method significantly outperforms traditional benchmarks, demonstrating its effectiveness in predicting engagement and supporting policy decisions. This research

advances user engagement analytics and policy learning by introducing an interpretable, data-driven approach for predicting short-term engagement. The proposed framework serves as a decision-support tool that enables online gaming platforms to optimize business strategies, improve user retention, and drive revenue growth by proactively addressing the challenges of user disengagement.

4 - Emotional Dynamics: the Nonlinear Impact of Sentiment Volatility on Review Helpfulness

Jiaqi Ren, Zhejiang University, Hangzhou, China, People's Republic of, Xixian Peng, Yifan Yu, Yutong Guo

Affective cues embedded in online reviews play a pivotal role in shaping perceptions of review helpfulness. Prior research has primarily examined static affective characteristics, such as sentiment valence, arousal, and discrete emotions. In practice, emotional expressions often vary dynamically over time rather than remaining constant. This work introduces a novel affective cue: sentiment volatility, which captures the emotional dynamics in online reviews. Drawing on emotions as social information (EASI) theory, we explore how sentiment volatility influences perceived review helpfulness through both affective and inferential processes. We employ a multimethod approach involving (1) an analysis of a real-world dataset, (2) a functional near-infrared spectroscopy (fNIRS) experiment, and (3) an online experiment. Results of the three studies reveal an inverted U-shaped relationship between sentiment volatility and perceived review helpfulness, driven by two mechanisms: emotional contagion (affective process) and conceptual processing fluency (inferential process). In addition, we find that for the affective process, the negative effect of low sentiment volatility on emotional contagion is attenuated among readers with high levels of emotional contagion susceptibility. Our findings advance existing literature by highlighting emotional dynamics in the online review context and offer practical implications for platforms, reviewers, and merchants.

Smooth and Convex Optimization

Job Market Showcase

Job Market Showcase

Chair: Alan Luner, Johns Hopkins University, Baltimore, 21210, United States

1 - Modern Convex Optimization & Hidden Convexity and Its Applications

Kevin Shu, California Institute of Technology, Pasadena, CA, United States

We often think about a dichotomy between convex and nonconvex optimization, the former being tractable and certifiably correct, and the latter being difficult but encompassing a much wider range of problems. This talk will present examples in which convex optimization can answer questions that do not on the surface seem to be convex, a surprisingly common phenomenon termed 'hidden convexity'. The two examples presented will be those of computer assisted design of algorithms and optimization over the manifold of rotation matrices, both of which arise in an array of applications and are far from being convex. First, we will describe how to construct first-order algorithms for optimization that have provably fast convergence rates using convex certificates of convergence, which are in some cases optimal with respect to strong metrics for convergence. Next, using ideas from topology, we show that optimization problems involving rotations of high-dimensional point clouds – i.e. optimization over the nonconvex set of rotation matrices -- can often be formulated as convex programs after a suitable low-dimensional projection; this is unlike the usual approach in which one 'lifts' a nonconvex problem to a convex one in higher dimensions. In both of these examples, the interaction with convex optimization facilitates mathematical guarantees for difficult optimization problems as well as fast algorithms for solving them.

2 - Spectral Methods for Polynomial Optimization

Elvira Moreno Ferreira, California Institute of Technology, Pasadena, CA, United States, Venkat Chandrasekaran

We propose a hierarchy of tractable relaxations based on spectral methods for polynomial optimization problems (POPs). Concretely, our hierarchy of spectral relaxations yields a monotonic sequence of bounds for the optimal value of a POP, each of which is computed as the minimum eigenvalue of a matrix obtained from the problem data. Because spectral methods are less computationally demanding than semidefinite programs, which underpin state-of-the-art techniques based on SOS certificates of non-negativity, our hierarchy provides an attractive alternative for obtaining bounds on large-scale problems. We identify the algebraic structure underlying a POP that makes it amenable to spectral relaxations, and we demonstrate the efficiency and applicability of our framework with numerical examples.

3 - A Performant Adaptive Linesearch-Free Subgame Perfect Gradient Method

Alan Luner, Johns Hopkins University, Baltimore, MD, United States

We present a highly performant gradient method for smooth convex optimization, drawing inspiration from several recent advances in the field. Our algorithm, the Adaptive Subgame Perfect Gradient Method (ASPGM) is based on the notion of subgame perfection, which provides a dynamic strengthening of the typical notion of minimax optimality. At each iteration, ASPGM makes a momentum-type update, optimized dynamically based on a (limited) memory/bundle of past function and gradient information. ASPGM is linesearch-free and fully adaptive due to its use of recently developed auto-conditioning, restarting, and preconditioning ideas. We show that ASPGM is performant on a wide range of problem classes and is competitive with BFGS and L-BFGS, the state of the art for these settings. Moreover, ASPGM maintains a certificate of solution quality, resulting in simple stopping criteria and restarting conditions.

1 - Bridging Human Limitations: the Impact of Robot-Assisted Surgery on Clinical Outcomes and Healthcare Equity

Sung Joo Kim, Purdue University, West Lafayette, IN, United States

As AI is reshaping healthcare procedures and outcomes, Robot-assisted surgery (RAS) represents a cutting-edge advancement designed to transcend human limitations in both physical and cognitive aspects of surgical procedures, promising significant improvements in clinical outcomes. In this study, we investigate the impact of RAS on surgeon performance and healthcare outcomes. Especially, we explore how RAS implementation mitigates healthcare disparities as well as lowers in-hospital mortality rates.

2 - Building AI with Ai: the Impact of Generative Technologies on Startup Teams and Ai Product Innovation

Dongwook Chun, McGill University, Montreal, QC, Canada, Taha Havakhor, Animesh Animesh

This study investigates how the integration of artificial intelligence (AI) as a product feature—rather than merely as a development tool—shapes entrepreneurial team formation across diverse product domains. Leveraging data from over 76,000 early-stage product launches on ProductHunt (2021–2023), the paper introduces the concept of domain-level AI Functionality, measuring the functional alignment between product descriptions and AI patent technologies using contextualized topic modeling and semantic similarity. Employing a shift-share instrumental variable approach, the analysis reveals that domains with higher AI functionality traditionally required larger teams due to elevated demands for domain-specific knowledge depth and AI complexity. However, following the widespread access to Generative AI (GenAI) tools like ChatGPT, this relationship weakens, especially in generative, competitive, and enterprise-facing domains, as GenAI lowers the labor intensity and technical barriers of AI integration. While GenAI democratizes AI-enhanced product creation for smaller teams and solo entrepreneurs, it also reduces product quality differentiation and diminishes conceptual novelty. The findings illuminate how AI functionality and generative technologies are reshaping human capital demands and innovation patterns in entrepreneurial ecosystems, offering implications for founders, investors, and policymakers.

3 - Hyperparameter Optimization and Algorithm Selection: Practical Techniques, Theory, and New Frontiers

Dravyansh Sharma, Toyota Technological Institute, Chicago, IL, United States

Machine learning algorithms operate on data, and for any task the most effective method depends on the data at hand. Hyperparameter optimization and algorithm selection are therefore crucial to ensure the best performance in terms of accuracy, efficiency, reliability, interpretability, etc.

4 - Generative AI, Human Expertise, and Scaling Law

Jie Zheng, Purdue University, West Lafayette, IN, United States, Mohammad Rahman, Yu Hu

Evaluation is a critical component in business for producing high-quality knowledge outputs. It is typically conducted by human experts, but this process is difficult to scale, and expertise takes time to develop—making it scarce and often insufficient to assess the growing volume of knowledge outputs within organizations, especially with the broad use of generative AI. With the advancement of large language models (LLMs), there is growing interest in understanding whether LLMs can perform evaluations that are consistent with expert judgment. Because evaluation requires a high level of expertise—including both domain knowledge and expert judgment—we investigate how adding these types of data affects LLM evaluation. We partner with a consulting firm and design a two-stage experiment. In the first stage, human experts evaluate negotiation strategy reports. In the second stage, LLMs of different sizes are used to evaluate the same reports, with prompts adding either domain knowledge or expert judgment data. Our results show that expert judgment data improves agreement with experts more effectively than domain knowledge. We further demonstrate that expert judgment and domain knowledge impact agreement through within-role and across-role uncertainty in LLMs in different ways. In particular, higher levels of both types of uncertainty in LLMs can predict lower agreement with expert evaluations. Based on this insight, we propose a method that leverages uncertainty to select data, thereby improving agreement between LLMs and experts when scaling data.

Building A Level 3 A311

Novel AI Applications and Perspectives

Job Market Showcase

Job Market Showcase

Chair: Junyi Sha, MIT, Cambridge, MA, United States

1 - Human Decision-Making in AI Task Augmentation

Joseph Sebastian, Rensselaer Polytechnic Institute, Troy, NY, United States

In an era of rapid advancements in Artificial Intelligence (AI), effective human-AI collaboration is essential for enhancing decision-making, particularly when tasks involve varying levels of payout. While AI can perform increasingly complex tasks, determining when humans choose to delegate to AI remains an open question. This study investigates how humans delegate image classification tasks to AI in high- versus low-payout scenarios, and how trust in AI and individual risk preferences influence this behavior. Drawing on theories of absorptive capacity, algorithm aversion, and human-AI complementarities, we hypothesize that (1) individuals are more likely to delegate in low-payout scenarios, (2) risk attitude moderates the delegation decision, and (3) trust in AI further conditions this relationship. We conduct a two-part randomized experiment where participants classify images themselves or delegate to an AI agent, under varying financial incentives. Preliminary results reveal that delegation patterns vary significantly by payout structure, risk aversion, and trust levels, offering new insights into how augmented intelligence can be optimized in future workplace settings. These findings have theoretical and practical implications for the design of AI-integrated workflows and decision-support systems.

2 - Rethink AI for Vehicle Routing: Towards Generalization and Sustainability

Zhuoli Yin, Purdue University, West Lafayette, IN, United States

Artificial Intelligence (AI) promises to reshape combinatorial optimization problems like Traveling Salesman Problem and Vehicle Routing Problem. However, current AI based approaches face two key challenges: limited generalizability to real-world instances and the high environmental cost of training large models. In this talk, I present (1) a novel method leveraging vision language models to perform vision guidance for the optimization process without task-specific training, and (2) a new evaluation framework for quantifying the net sustainability benefits of applying AI to real-world vehicle routing.

3 - Productgpt: a Generative Model of Consumer Decision Dynamics in Limited-TIME Product Offerings

Jin Miao, The University of Texas at Dallas, Richardson, TX, United States, Fanglin Chen, Ying Xie

Managers frequently offer limited-time products across various industries, yet few studies examine consumers' dynamic decisions to guide managerial choices about reissuing previous products or introducing new ones. We develop *ProductGPT*, a novel deep generative pre-trained Transformer designed to predict sequential purchase decisions in limited-time product settings.

Three key features differentiate our *ProductGPT* from standard Transformer models. First, it uses triplet input tokens simultaneously encapsulate decision history, the supply-side sequence of limited-time products, and the demand-side sequence of observed decision outcomes. This approach enables *ProductGPT* to capture the rich and meaningful product representations for all products (i.e., both limited-time and always-available products) in the assortment. Second, using the encoded long-range and short-range contexts, *ProductGPT* exclusively predicts consumer decisions. During the inference phase, we can leverage the model to generate consumer decision sequences under alternative limited-time product schemes, thus providing managers a decision tool to help design limited-time products. Third, *ProductGPT* incorporates product features as covariates, enabling managers to forecast sales of new limited-time products through feature-based product embeddings.

We apply *ProductGPT* to a unique 20-month transaction dataset of video game loot boxes. Our model consistently outperforms several sophisticated benchmark models in sequential purchase predictions. We demonstrate its ability to forecast aggregate sales, discover behavioural patterns, and support product sequencing strategies.

4 - AI Tailoring: Evaluating Influence of Image Features on Fashion product Popularity

Junyi Sha, MIT, Cambridge, MA, United States

Identifying key product features that influence consumer preferences is essential in the fashion industry. In this study, we introduce a robust methodology to ascertain the most impactful features in fashion product images, utilizing past market sales data. First, we propose the metric called "influence score" to quantitatively assess the importance of product features. Then we develop a forecasting model, the Fashion Demand Predictor (FDP), which integrates Transformer-based models and Random Forest to predict market popularity based on product images. We employ image-editing diffusion models to modify these images and perform an ablation study, which validates the impact of the highest and lowest-scoring features on the model's popularity predictions. Additionally, we further validate these results through surveys that gather human rankings of preferences, confirming the accuracy of the FDP model's predictions and the efficacy of our method in identifying influential features. Notably, products enhanced with "good" features show marked improvements in predicted popularity over their modified counterparts. Our approach develops a fully automated and systematic framework for fashion image analysis that provides valuable guidance for downstream tasks such as fashion product design and marketing strategy development.

Topics in Customer Choice

Job Market Showcase

Job Market Showcase

Chair: Zhi Wang, University of Texas at Austin, Austin, TX, United States

1 - Customer Preferences in Multi-Channel Services

Omer Berk Olmez, Baruch College, Graduate Center, CUNY, New York, NY, United States

As multi-channel services become more common, understanding the value customers place on virtual and in-person services has become increasingly important. Using data from a provider with in-person and virtual channels, we examine how service delivery channels and attributes—such as duration and distance—shape customer choices.

2 - Choice Modeling, Assortment Optimization, and Estimation when Customers are Non-Rational: Multinomial Logit Model with Non-Parametric Dominance

Yuheng Wang, Cornell University, New York, NY, United States, Dmitry Mitrofanov, Huseyin Topaloglu

Capturing non-rational choice behavior is crucial for accurately predicting customer choices and optimizing decision-making processes, as traditional choice models often do not capture non-rational factors that influence purchasing decisions. In this paper, we study a powerful two-stage choice modeling framework to capture a diverse array of non-rational customer behaviors. More specifically, we analyze a choice model where customers first use non-parametric dominance relationships to narrow down their options, and subsequently make a choice from the shortlisted products using the multinomial logit model. This choice model goes beyond the random utility maximization (RUM) framework by capturing a broad range of non-rational customer behaviors, including the decoy effect, choice overload, and preference cycles. Remarkably, we establish a clear and insightful connection between our choice model and the ranking-based framework that is equivalent to the RUM class. We demonstrate that our model can be represented using a ranking-based structure with negative 'probability' assigned to specific rankings. We then study the assortment optimization problem under this model, showing that it can be solved using a linear program. To fully operationalize this two-stage model, we also introduce its two-class version that captures the heterogeneity of customers in their propensity to deviate from the RUM framework. We demonstrate that the assortment optimization problem under this two-class variant is strongly NP-hard. Additionally, we propose an estimation framework to infer the dominance relationships in our model. Our numerical experiments highlight the model's superior predictive performance compared to RUM benchmarks and underscore its practical applicability in identifying revenue-maximizing assortments.

3 - Neural-Network Based Choice Model with Statistical and Optimality Guarantees

Zhi Wang, University of Texas at Austin, Austin, TX, United States, Rui Gao, Shuang Li

Discrete Choice Model has been a fundamental problem in operations, marketing, and economics to understand consumer choice behavior when provided a set of alternatives. The talk focuses on using neural networks for modeling rational choices and beyond, which tackles not only statistical properties and but also optimality guarantees. We demonstrate that overparameterization does not lead to overfitting when appropriate norm or entropy-regularization is applied. We prove that SGD-type algorithm achieves global convergence, despite the non-convexity of the problem. Empirical studies on datasets substantiate our theoretical findings.

Machine Maintenance

Job Market Showcase

Job Market Showcase

Chair: Edikan Udofia, Colorado School of Mines, Lakewood, CO, United States

1 - Towards a Foundation Model for End-To-End Maintenance Optimization Using Sensor Data

MOHAMMAD BADFAR, Wayne State University, Detroit, MI, United States, Iman Kazemian, Murat Yildirim, Ratna Chinnam

Maintenance operations often dominate operational budgets—unplanned downtimes alone can cost millions per hour in equipment replacement and operational interruptions. Advances in sensor technologies enabled condition-based maintenance, where sensor-driven predictions on asset conditions inform optimal decision-making, yet the widespread deployment of such systems remains limited due to siloed, and expert-driven solutions that split into separate “predict” and “optimize” phases. We introduce ATOM, an end-to-end attention-based early-stage foundation model that learns directly from raw, multivariate sensor streams to prescribe optimal actions under real-world constraints, without ever needing to predict asset conditions. Built on a lightweight multi-head encoder-decoder, ATOM embeds resource limits, visit costs and crew availability via simple attention masks, collapsing forecasting and scheduling into a single policy network. On commercial Li-ion battery fleets, ATOM reduces total maintenance cost by 22–35% versus a state-of-the-art Predict-then-Optimize (PtO) pipeline, while closing over 90% of the gap to an Oracle with perfect foresight. We further show that by pretraining ATOM across randomly sampled cost structures, a single transferable agent can adapt to new cost regimes without retraining—demonstrating early-stages of a foundation-model behavior. Beyond batteries, our framework provides a four-step recipe for any domain that must convert streaming data into constrained decisions: (1) ingest raw features, (2) encode constraints via masks, (3) train on a task-aligned cost function, and (4) deploy a unified policy. Potential applications range from supply-chain replenishment to clinical resource scheduling and renewable-energy dispatch. By democratizing complex optimization behind an attention-powered interface, ATOM paves the way for foundation-model economics in operations across industries.

2 - Optimal Control of a Partially Observable Markov Deterioration Process

Cong Yang, University of British Columbia, Vancouver, BC, Canada, Hao Zhang

We study the optimal maintenance of a machine whose state is unobservable and deteriorates according to a discrete-time finite-state Markov process. At the beginning of any period, the machine may fail, which is self-announcing and will trigger an immediate corrective replacement. Otherwise, the decision maker can choose from three actions—production, inspection, and preventive replacement. Production is the normal action which continues the deterioration process; inspection reveals the machine state (deterioration level) perfectly; and replacement resets the machine to its best state. The model can be easily extended to incorporate more real-world features such as two types of failures and multiple replacement or repair options. It also describes an inventory management problem with unobserved inventory (or unrecorded demands). Adopting a relatively new methodology from the area of partially observable Markov decision processes, we identify several elegant structures of the optimal solution, which can be conveniently represented by graphs with multiple absorbing cycles. The optimal policies possess desired properties such as “dynamically scheduled inspections” and “postponed replacement after an inspection.” We develop a policy iteration algorithm to find the optimal solution exactly in finite time. This study fills a visible gap in the research of partially observable machine maintenance problems as well as partially observable inventory control problems.

3 - Approaches to Evaluate Condition Monitoring Systems for Risk Management in Manufacturing

Mehdi Dadfarnia, University of Maryland-College Park, College Park, MD, United States

Condition monitoring involves detecting, diagnosing, or predicting faults or failures in industrial equipment. Given advances in underlying AI solutions and IoT-based technologies, condition monitoring can rapidly improve maintenance processes. This talk discusses evaluation techniques and frameworks that justify investment in condition monitoring for manufacturing maintenance applications. This talk will present state-of-the-art evaluation methods for condition monitoring in industrial maintenance and discuss the challenges and current limitations of these methods. After presenting a procedural framework for evaluating the financial and engineering risks and benefits of condition monitoring systems in industrial applications, this talk introduces and compares simulation-based and analytical evaluation methods specific to monitoring for discrete-part manufacturing maintenance.

4 - Industrial Scale Data Analysis (Predictive Modeling of Force and Wear In Hot Rolling Continuous Steel Casting)

Edikan Udofia, Colorado School of Mines, Lakewood, CO, United States

This study develops a data analytics framework for predicting roll wear in hot steel rolling mills to optimize maintenance scheduling. We analyzed industrial datasets containing over 1GB of production data with 200+ variables per record to build predictive models for roll wear patterns.

Job Market Showcase

Chair: Harriet Jeon, The Wharton School, University of Pennsylvania, Philadelphia, PA, United States

1 - Incentivizing Smallholder Supplier Sustainability Under Behavioral Regularities**Yuan Shi, MIT, Boston, MA, United States, Iskandar Siregar, Yanchong Zheng**

Theoretical studies of sustainable farming incentives often assume rational decision-making, yet smallholder farmers exhibit behavioral biases that impact their decisions. Large-scale field experiments in this domain face measurement difficulties and are long term, high-stake efforts, which limits iterative testing of incentive structures. We address this by using *laboratory-in-the-field* experiments with Indonesian palm oil farmers, simulating real-world decision-making while maintaining experimental control. Results from our first experiment reveal key deviations from rational models: production-linked price premium incentives that are nearly optimal under the rational model did not outperform simple fixed payments due to behavioral factors including bounded rationality, cost aversion, and social preferences. To address this, we develop a behavioral incentive design framework, refining incentive structures and experimental design to align with observed decision-making patterns. In the redesigned second experiment, behaviorally calibrated premium contracts increased permanent sustainable adoption from 56% to 69% compared to fixed payments at no extra cost. Our findings highlight the need for empirically grounded, behaviorally informed incentives to enhance sustainability in supply chains and offer actionable insights to policymakers and practitioners.

2 - Adopting 'Green' Shareholder Proposals Can Improve Firm Operations**Hyungchan Cho, University of Michigan, Ann Arbor, MI, United States, Damian Beil, Andrew Wu**

This study examines whether the passage of environmental, social, and governance shareholder proposals leads to changes in firm operational performance. We show that firms whose environmental proposals pass experience statistically significant gains in operating efficiency: inventory turnover accelerates, cash conversion cycle shortens, and gross margin return on inventory rises, with effects emerging 3-5 years post-passage. In contrast, social and governance proposals display no consistent operational impact.

To understand the underlying channels, we first note that narrative disclosures from firms adopting environmental proposals often highlight commitments to invest in cleaner technologies, renewable power, and waste-reduction systems. Our analysis corroborates this, showing that treated firms significantly increase capital expenditures on property, plant, and equipment. Concurrent with these investments, we find a significant increase in asset retirements. This pattern suggests that the capital outlays are directed towards modernization and retrofitting rather than expansion. The resulting modernized asset base provides a plausible explanation for the observed delayed gains in operational performance.

The analysis leverages a proposal-level voting database for US public companies and applies a regression-discontinuity design; close wins and close losses supply quasi-random variation in adoption. We estimate dynamic treatment-on-the-treated effects by tracking firm outcomes from the meeting year through five subsequent fiscal years.

Our results suggest that the substance of a proposal matters: environmental measures translate into operational change, whereas social and governance measures do not. By linking shareholder activism to longer-run operating fundamentals, the paper provides a causal framework for understanding how specific ESG-driven mandates translate into firm-level operational performance.

3 - Rented Today, Bought Tomorrow: Buyout Pricing in the Circular Economy**Borja Apaolaza, The Wharton School - University of Pennsylvania, Philadelphia, PA, United States, Gerard Cachon, Santiago Gallino, Antonio Moreno**

Consumer preferences are shifting away from traditional ownership toward models that emphasize access, flexibility, and sustainability, fueling the growth of circular economy practices across industries. In the fashion sector, rental subscription services such as ThredUp, Nuuly, and Rent the Runway exemplify this transition by offering customers the ability to rent garments for a fixed monthly fee, with the added option to purchase rented items. This hybrid rental-sale model introduces a complex pricing challenge: setting buyout prices that balance immediate sales revenue with potential future rental income, while accounting for item-specific attributes such as popularity, condition, and customer price sensitivity.

In collaboration with a leading U.S. fashion rental company, we develop, estimate and validate a data-driven framework for optimizing buyout prices in this dual-revenue setting. We model the system using a Markov Decision Process (MDP) that captures the dynamics of garment rental, sale, and attrition, allowing us to prescribe revenue-maximizing prices while accounting for the complexities of the system. We calibrate our framework using real-world rental, purchase, and inventory data from our industry partner.

We validate our framework through extensive simulations and show that it significantly improves profitability compared to existing practices and alternative benchmarks. We estimate that the proposed pricing policy increases revenue by 3.1% over the company's current approach. Our analysis further highlights the importance of accounting for garment condition, and underscores the value of buyout options in managing inventory and generating additional income. Lastly, we propose a heuristic approach that delivers near-optimal performance with substantially reduced computational complexity.

1 - Limits of Hegselmann-Krause Models**Aditya Gopalan, UIUC, Urbana, IL, United States, Partha Dey, Rasoul Etesami**

Hegselmann-Krause models are a localized, distributed averaging dynamics on spatial data. A key aspect of these dynamics is that they lead to cluster formation, which has important applications in geographic information systems, dynamic clustering algorithms, and social networks. For these models, the key questions are determining whether there exists a fixed point, and if so, characterizing it. In this talk, we will discuss two recent/ongoing works.

In the first, we discuss new results towards the “2R-Conjecture” for the Hegselmann-Krause model, for which no meaningful progress, or even any precise statement, has been made since its appearance in 2007. We provide, among other results, a proof that the expected cluster size converges to 2R and a statement of a stronger result about the convergence of the fixed points as the initial intensity tends to infinity, which is supported by simulation. In the second,

we discuss the existence of a fixed point of a stochastic variant of the Hegselmann-Krause dynamics which provides insights into algorithm development for large-scale dynamic clustering.

The key methodological contribution is to consider the dynamics as an infinite-dimensional problem on the space of point processes, rather than on finitely many points. This allows us to leverage stationarity and certain other symmetries to obtain the results. These techniques do not have finite-dimensional analogues.

2 - Designing Data Science Contests: the Role of Training Vs Test Splits

Ping-Chieh Huang, University of California-San Diego, La Jolla, CA, United States, Zhe Zhang, Sanjiv Erat

Companies organize data science contests to source innovative machine learning solutions for business operations. Using contests hosted on Kaggle as a motivating example, we formulate a model of data science contests where the organizer splits the data into a training part that is provided to contestants to build candidate models, and a testing part that is reserved privately to evaluate the submitted models. Previous literature in statistics suggests using intermediate data splits to strike a balance between having enough training data and being able to reliably rank models. However, by considering how participants choose their modeling approaches and the incentives they face in data science contests, we identify a new third effect of the split ratio. When intermediate splits are used — where the firm's evaluation of model performance is most reliable — contestants actually have the strongest incentive to submit “sub-optimal” models with higher variability in order to gain an advantage in the contest. An empirical examination of the past five years of Kaggle contests shows results that are consistent with our theoretical findings. Thus, an immediate implication of our model is that such intermediate split ratios advocated in prior statistics literature might result in the firm accurately choosing from a set of inaccurate submitted models.

3 - Practical Portfolio Optimization for Parlay Betting on Simultaneous Events

Jeff Sylvestre-Decary, University of Connecticut, Storrs, CT, United States, David Bergman, Bin Zou

This study addresses the challenge of optimal portfolio allocation in a classical betting setting, assuming the bettor seeks to maximize log-utility. While the Kelly Criterion is well-established as the optimal allocation for a single bet, questions remain open regarding how to proceed when considering multiple bets simultaneously. Building on prior literature, we present theoretical results on optimal parlay construction and propose a scalable logic-based Benders decomposition algorithm. Our formulation explicitly incorporates practical constraints faced by bettors—such as cardinality constraints on the number of bets placed and limits on parlay size—making the approach applicable in real-world sportsbook environments. We evaluate the algorithm's performance on both synthetic data and real-world sports betting instances, demonstrating its potential to enhance parlay strategies.

4 - Optimizing Mobility and Fairness in Public Housing Allocation

Yifeng Cao, Sauder School of Business, University of British Columbia, Vancouver, BC, Canada, Yichuan Ding, Daniel Granot, Hao Zhang, Weihua Zhang

We study a centralized public housing allocation problem, where a housing authority must assign limited housing units to applicants, including both move-in and transfer requests. Motivated by operational challenges faced by BC Housing, we propose a dynamic allocation framework that optimizes both mobility and fairness, where mobility is defined as the ease with which housing requests are fulfilled. Using and extending the matching queue framework of Gurvich and Ward (2014), we derive the optimal policy and adopt their policy for optimal review periods. In each period, the problem is formulated as a circulation problem with convex costs, solvable using a greedy algorithm. We prove that our algorithm is asymptotically optimal as arrival rates grow large, converging to an imbalance-based lower bound at an improved rate of $O(1/n^{1/3})$. Additionally, we determine the optimal priority to assign to transfer requests relative to move-in requests to achieve the optimal efficiency-fairness trade-off. Numerical experiments using real-world BC Housing data and simulations demonstrate that our algorithm achieves near-optimal performance, with solutions closely approximating the clairvoyant benchmark.

Decision Making in Uncertain Dynamic Environments

Invited Session

Computing Society

Chair: Aras Selvi, Princeton University, Princeton, NJ, United States

1 - Breaking the Curse of Multiagency in Robust Multi-Agent Reinforcement Learning

Laixi Shi, California Institute of Technology (Caltech), Pasadena, CA, United States

Standard multi-agent reinforcement learning (MARL) algorithms are vulnerable to sim-to-real gaps. To address this, distributionally robust Markov games (RMGs) have been proposed to enhance robustness in MARL by optimizing the worst-case performance when game dynamics shift within a prescribed uncertainty set. RMGs remains under-explored, from reasonable problem formulation to the development of sample-efficient algorithms. Two notorious and open challenges are the formulation of the uncertainty set and whether the corresponding RMGs can overcome the curse of multiagency, where the sample complexity scales exponentially with the number of agents. In this work, we propose a natural class of RMGs inspired by behavioral economics, where each agent's uncertainty set is shaped by both the environment and the integrated behavior of other agents. We first establish the well-posedness of this class of RMGs by proving the existence of game-theoretic solutions such as robust Nash equilibria and coarse correlated equilibria (CCE). Assuming access to a generative model, we then introduce a sample-efficient algorithm for learning the CCE whose sample complexity scales polynomially with all relevant parameters. To the best of our knowledge, this is the first algorithm to break the curse of multiagency for RMGs, regardless of the uncertainty set formulation.

2 - Learning Causal Structure to Improve Sample Complexity in RL

Lily Xu, Columbia University, New York, NY, United States

One of the biggest barriers to real-world implementation of reinforcement learning (RL) algorithms is high sample complexity, especially when the action and state space are high in dimension. Here, we consider settings with multiple actions that each impact different subsets of state variables, which models many practical problems in healthcare, environmental management, and more. In many cases, the underlying structure is unknown a priori. We provide an approach to train a RL policy that simultaneously learns the underlying graph structure, enabling us to achieve strong performance within a shorter horizon.

3 - A Minimax Shrinkage Scheme for Wasserstein Distributionally Robust Optimization

Lingjun Meng, Imperial College Business School, London, United Kingdom, Ryan Cory-Wright, Wolfram Wiesemann

Wasserstein distributionally robust optimization (DRO) is a popular paradigm for decision-making under distributional ambiguity with a strong out-of-sample performance guarantee. While Wasserstein DRO sometimes admits tractable deterministic reformulations, it is still practically challenging to solve in many relevant applications. To enhance the scalability of Wasserstein DRO, this work proposes a scalable approximation algorithm for Wasserstein DRO. Namely, we interpolate between the optimal solution to a sample average approximation problem (i.e., a Wasserstein DRO problem with an ambiguity radius of zero) and a maximally robust optimization problem (i.e., a Wasserstein DRO problem with an ambiguity radius of infinity) to approximate the optimal Wasserstein DRO solution. We certify the quality of our solutions via a priori performance guarantee by providing an upper bound for the distance between the interpolated solution and the Wasserstein DRO solution. Additionally, we propose an instance-specific posteriori performance guarantee by interpolating both the primal and dual Wasserstein DRO problems and computing the gap between the primal and dual objective using the interpolated solution. Moreover, we develop a tractable bisection search scheme for selecting the optimal interpolation parameter. Finally, we demonstrate the practical efficacy of our approximation in several high-dimensional settings drawn from the finance and supply chain literature.

4 - Inventory Commingling on An E-Commerce Platform

Hanqi Wen, Ross School of Business, University of Michigan, Ann Arbor, MI, United States, Izak Duenyas, Joline Uichanco

Inventory commingling is an emerging e-commerce fulfillment strategy that is transforming how marketplace platforms with fulfillment services manage third-party seller inventories. This approach maintains identical products from multiple sellers in a shared virtual pool—where each unit is interchangeable regardless of physical location or original seller—thereby reducing the platform's shipping costs. While sellers benefit from the streamlined handling when commingling, they also face the risk that their customers may receive defective or substandard units from less scrupulous sellers exploiting the system.

We develop a two-stage game-theoretic model in which the platform first sets its fulfillment fee, and sellers with heterogeneous product qualities then decide whether to commingle, maintain separate inventories, or exit the platform. Our analysis reveals that lower-quality sellers are more likely to “free-ride” by commingling, introducing product quality risks that incentivize higher-quality sellers to keep separate inventories. Comparing equilibrium outcomes with and without commingling, we find that commingling consistently enhances platform profitability, although its impact on fulfillment fees and seller profits varies with market conditions. Implementing commingling in selective markets can ensure that commingling does not compromise product quality while realizing operational efficiencies. However, higher-quality sellers may suffer financially when the fulfillment fee rises to capture surplus gains.

5 - Going from a Representative Agent to Counterfactuals in Combinatorial Choice

Yanqiu Ruan, Singapore University of Technology and Design, Singapore, Singapore, Karthyek Murthy, Karthik Natarajan

We study decision-making problems where data comprises points from a collection of binary polytopes, capturing aggregate information stemming from various combinatorial selection environments. We propose a nonparametric approach for counterfactual inference in this setting based on a representative agent model, where the available data is viewed as arising from maximizing separable concave utility functions over the respective binary polytopes. Our first contribution is to precisely characterize the selection probabilities representable under this model and show that verifying the consistency of any given aggregated selection dataset reduces to solving a polynomial-sized linear program. Building on this characterization, we develop a nonparametric method for counterfactual prediction. When data is inconsistent with the model, finding a best-fitting approximation for prediction reduces to solving a compact mixed-integer convex program. Numerical experiments based on synthetic data demonstrate the method's flexibility, predictive accuracy, and strong representational power even under model misspecification.

The Practice Section of Informs

Chair: Yaniv Mordecai, Amazon, Bellevue, WA, United States

1 - Exploring the AI Frontier in Optimization Research

Michael Wagner, University of Washington, Seattle, WA, United States, Rohit Malshe

We explore the ability of AI models to solve challenging optimization problems, focusing on evaluating their mathematical modeling skills rather than coding or writing abilities. The problems are taken from publicly available sources as well as originally written problems, from an introductory doctoral optimization course taught by Professor Michael Wagner at the University of Washington. The topics span various areas such as linear and integer programming, network optimization, dynamic programming, convex optimization, semidefinite programming, and robust optimization. We consider the most powerful AI models available in specific families: Anthropic's Claude 3 Opus, OpenAI's o1 pro, and Deepseek's R1. We ask the AIs to solve the problems, which are then assessed by Professor Wagner. We find that Opus solves 2/12 correctly, Deepseek-R1 solves 10/12 correctly, and o1 pro solves 11/12 correctly.

2 - Optimization Models Explained - Optix

Gokce Kahvecioglu, Amazon, Bellevue, WA, United States, Jin Ye, Ling Zhang

The opacity of decision-making processes in optimization models often hinders stakeholder trust and engagement. This paper introduces OptiX, a novel multi-agent large language model (LLM) framework to enhance the explainability of optimization models. OptiX addresses the critical gap between the technical capabilities of optimization models and their practical application, particularly in Amazon's vast supply chain ecosystem. OptiX is designed to provide clear, user-friendly narratives explaining optimization outputs to end-users with both technical and non-technical backgrounds. It highlights binding operational constraints, elucidates trade-offs guiding the model's recommendations, and assists scientists in rapid troubleshooting. The framework's architecture prioritizes simplicity and scalability, allowing it to adapt to various optimization models by consuming common artifacts such as solver logs, model formulations, and solutions, as well as science papers and technical documents. We assess the effectiveness of OptiX across a diverse set of optimization problems widely used at Amazon, including an high-impact optimization model in production where we allow the end-users interact directly with OptiX. Through systematic assessment by domain experts, our results demonstrate that OptiX generates explanations comparable in quality to those provided by human experts while delivering responses significantly faster.

3 - Assessing Vehicle Cleanliness Using Vision-Language Models

Girik Malik, Amazon, Austin, TX, United States, Jin Ye

As vehicle cleanliness becomes a critical aspect of safe vehicle operations, the demand for automated, objective solutions to assess and monitor cleanliness have become important. This research presents an innovative image-based scoring system designed to provide stakeholders with actionable insights into vehicle cleanliness. We demonstrate the efficacy of zero-shot learning in rating images based on their cleanliness levels. Furthermore, we demonstrate that our method can effectively align with human judgment based on only a limited number of in-context learning examples and produces results consistent with human scoring. By employing AI and image recognition techniques, the proposed system addresses the limitations of current methodologies, facilitating more efficient, safe, and hygienic vehicle operations. The system's potential extends beyond cleanliness monitoring, encompassing scalability for other applications such as vehicle damage detection. Future research will concentrate on fine-tuning VLM models to enhance human alignment with real-world scenarios and expanding the model's capabilities to operations beyond vehicle cleanliness through automated AI agents.

Overcoming Challenges Moving from Data to Decisions

Invited Session

Practice Track

Chair: Somayeh Dejbord, Delta Air Lines, Atlanta, United States

1 - On TIME Every Flight: Saving Delays with Delta's Smart Gating

Ian Bailie-Sinal, Delta Air Lines, Atlanta, GA, United States

In the U.S. airlines' fiercely competitive landscape, operational performance is increasingly critical in meeting every customer's expectation of an on-time arrival. However, increases in flight volume and network complexity have made it difficult to synergize small operational decisions, stretching the human operator's ability to make globally optimal decisions in service of on-time performance. In this presentation, the Delta Air Lines (DAL) decision science team will detail how developing and implementing a flexible optimization model for gate assignments has helped address the scale and complexity of driving operational performance in Atlanta (ATL), the world's largest passenger airport. This talk will touch on both the technical challenges of building an at-scale optimization tool in DAL's largest hub, as well as the business challenges associated with developing a product that cuts across multiple operational divisions.

2 - Building the Foundation: Infrastructure for Data-Driven Decision at Scale

Arpit Rana, ACV Auctions, Buffalo, NY, United States

This talk will explore the challenges and lessons learned in designing a collaborative, scalable, and trusted data warehouse infrastructure to drive decision-making at ACV. Built on top of **Google BigQuery**, our OLAP-style architecture supported modular data models tailored for downstream reporting, forecasting, and machine learning initiatives.

We'll cover how the team implemented robust CI/CD practices using GitHub, Jenkins and Terraform to ensure consistency and maintainability, while orchestrating ELT workflows through Airflow to streamline and monitor data processing. BigQuery served as the analytical engine powering fast, reliable access to business-critical data.

Through real-world examples, we'll demonstrate how this modern data stack enabled analytics engineers, data scientists, and business stakeholders to identify cost inefficiencies, uncover operational insights, and drive product innovation through data-informed decisions.

3 - Practical Lessons from Evolving Lyft's Experimentation Platform

Anahita Hassanzadeh, Lyft, San Francisco, CA, United States

In this talk, we'll share practical lessons from building and scaling Lyft's experimentation platform and decision-making processes. We'll discuss challenges in scaling computational workflows, and the steps we've taken to move from data to decisions quickly, consistently, and with confidence.

4 - From Runway Configs to Taxi Time: a Seq2seq LSTM Approach at Delta Hubs

Zack Berman, Delta Air Lines, Atlanta, GA, United States, Benjamin Seavoy, James Grooms

Every day in the United States, over 45,000 flights take to the skies, with peaks exceeding 5,400 simultaneous aircraft. In this highly complex, safety-critical environment, even small gains in operational efficiency yield substantial cost savings and on-time performance improvements. To modernize core planning functions, Delta Air Lines has developed two complementary machine-learning models that forecast key surface-operations metrics hours in advance.

The first model predicts **Taxi-Out Time**, the interval between gate pushback and takeoff, using gradient-boosted decision trees trained on historical flight, airport, and weather data. Early taxi-out estimates enable optimized block-buffer allocation, more accurate fuel planning, and proactive recovery strategies under adverse conditions.

The second model forecasts **Runway Configuration** at major hub airports by leveraging a Long Short-Term Memory (LSTM) neural network. Ingesting high-dimensional meteorological and traffic-flow inputs, it accurately predicts which runway sets will be active several hours ahead, reducing surface-congestion risk and improving coordination between airline dispatch and air-traffic management.

Together, these applications illustrate how predictive analytics can drive measurable improvements in throughput and delay reduction. Attendees will learn model-development best practices, integration challenges in a regulated domain, and a roadmap for extending forecasting to other operational areas, forging a data-driven blueprint for next-generation airline planning.

Designing Smarter Urban Transit Systems

Contributed Session

Contributed

Chair: Tina Radvand, University of Illinois at Urbana- Champaign, Urbana, IL, United States

1 - Equitable Transportation Network Design for Signal-Free Smart Intersections

dan zhu, National University of Singapore, Singapore, Singapore, Tingting Xie, Yang Liu, Napat Rujeerapaiboon

Intersections often become bottlenecks, causing delays due to stop-and-go operations. Connected and autonomous vehicles (CAVs) promise smoother navigation through signal-free smart intersections. However, during the gradual transition from human-driven vehicles (HVs) to CAVs, we propose a hybrid intersection design (HID) that strategically integrates signal-free smart intersections with traditional signal-based ones by optimizing smart intersection locations and signal timings. Recognizing that HID may induce distributional welfare effects, especially disadvantaging HV users, we develop four bi-level programming models incorporating ethical principles—utilitarian, sufficient, difference, and maximax—to address equity concerns. In each model, transportation planners determine equitable HID decisions at the upper level, while travelers make user-optimal route choices at the lower level. We formulate the lower-level problem as a network equilibrium with embedded signal-free smart intersections under mixed traffic and derive its equivalent variational inequality (VI) formulation, proving VI solution existence. Notably, we show that under the difference principle, no traveler is worse off compared to fully signal-based control. To solve the models, we reformulate them as single-level mathematical programs with equilibrium constraints (MPECs) and approximate them by mixed-integer linear programs (MILPs). We further develop an efficient breakpoint selection technique and propose a modified augmented Lagrangian multiplier (MALM) approach to evaluate MILP solution quality. Numerical experiments validate the high effectiveness of the MILP solutions, achieving small optimality gaps (~1%), and show that HIDs significantly reduce travel times, particularly when CAV penetration reaches 80%. Moreover, signal-free smart intersections are preferably allocated to locations that experience severe signal and/or queue delays under signal-based intersection control.

2 - Optimal Micro-Transit Zoning Problem

Samitha Samaranayake, Cornell University, Ithaca, NY, United States, Hins Hu, Hongyi Jiang, Rhea Goswami

Micro-transit services offer a promising solution to enhance urban mobility and access, particularly by complementing existing public transit. However, effectively designing these services requires determining optimal service zones for the on-demand shuttles, a complex challenge often constrained by operational budgets and transit agency priorities. In our recent work, we propose two frameworks for designing optimal micro-transit service zones with an objective of maximizing served demand. The first framework is a novel two-phase algorithm. In Phase 1, it efficiently generates a comprehensive set of valid candidate zones, leveraging the notion of shareability graph, while in Phase 2, it formulates the selection of the optimal zones as a Budget-Constrained Weighted Maximum Coverage Problem, which is easily solvable via integer programming. The second framework adopts a column generation approach, providing exact solutions and allowing integration of pricing heuristics for improved efficiency. We evaluate both frameworks on synthetic and real-world datasets, validating their effectiveness and scalability and demonstrating their superior performance compared to a baseline algorithm.

3 - A Goal Programming Approach for Optimizing Microtransit in Rural Areas

Tahmina Sultana, Clemson University, Clemson, SC, United States, Pamela Murray-Tuite

Limited access to dependable and adaptable transit remains a major barrier in rural areas across the United States. We propose a shared microtransit optimization model developed to improve mobility where traditional fixed-route systems are insufficient. Designed from both user and provider perspectives, the model balances passenger needs with operational efficiency. The model has three core goals: minimizing unserved ride requests, passenger travel time, and overall operational costs. It operates over discrete time steps. Passenger assignments are made based on origin-destination needs, time windows, and vehicle capacity. This model offers a practical tool for transit and demand response service planners and researchers aiming to develop flexible transportation solutions in rural regions.

4 - A Modeling Framework to Generate Activity-Based Travel Demand from Trip-Based Model

Yueshuai He, University of Louisville, Louisville, KY, United States, Eronmonsele Esekhaigbe, Lihui Bai

Activity-based models (ABMs) are widely recognized as the state-of-the-art approach for travel demand forecasting, offering detailed representations of individual behavior through interdependent sequences of activities. While ABMs offer clear advantages over traditional trip-based models—especially for evaluating complex policies and long-range planning—they remain underutilized due to extensive data and computational demands. This study presents a modeling framework for generating activity-based travel demand by leveraging outputs from an existing trip-based model. The objective is to support the broader adoption of ABMs while maintaining analytical rigor.

A case study is conducted for the Kentuckiana Regional Planning & Development Agency (KIPDA). Using the 2000 KIPDA household travel survey as a behavioral foundation, the framework begins with the generation of a synthetic population for the target year using iterative proportional fitting algorithm, aligning American Community Survey data with key socioeconomic and travel-related characteristics. Next, unique activity chains are derived at the individual level from the 2000 KIPDA household travel survey and linked to demographic profiles. These chains are expanded across the calibrated synthetic population to replicate representative travel patterns. Finally, a maximum likelihood optimization model is developed to assign spatial locations to each activity in a way that matches the origin-destination patterns from the trip-based model.

By reusing legacy survey data and existing model infrastructure, this framework offers a cost-effective, scalable pathway for researchers to transition toward more behaviorally realistic and policy-sensitive demand models across diverse geographic regions.

5 - Optimization of a Feeder Transit System Under Different Market Regimes

Jiaqing Lu, Florida State University, Tallahassee, FL, United States, Qianwen Guo

This research addresses the critical need for optimizing feeder transit systems that connect expanding suburban areas to major transit hubs, a challenge exacerbated by increasing urban population and traffic congestion. The study focuses on determining optimal values for key planning parameters, including feeder line density within a linear transportation corridor, stop spacing along routes, fare structures, and service headway. These parameters are optimized under distinct market regimes, specifically operator profit maximization and social welfare maximization. Two analytical optimization models are developed, incorporating an elastic travel demand function sensitive to service attributes. These models rigorously explore the intricate relationships between suburban population distribution, the design of transit lines and stop configurations, and overall system performance. A significant contribution of this work is the explicit consideration of different fare schemes (zone-based and distance-based fares) within the optimization framework. The research systematically investigates how varying population densities influence optimal line and stop spacing strategies (e.g., uniform versus uneven spacing) and how these parameters, in turn, affect operator profit and social welfare. Furthermore, the study will apply these proposed maximization models to two real-world feeder transit systems: the services in Denton County and Miami-Dade County. This application aims to determine optimal operational parameters tailored to the specific characteristics and diverse scales of these transit environments, thereby demonstrating the models' practical applicability for enhancing feeder service efficiency and effectiveness.

6 - How Fare Capping Affects Transit Ridership and Social Welfare? An Optimization Approach with Elastic and Spatially Distributed Demand

Ziyue Li, FAMU-FSU College of Engineering, Tallahassee, FL, United States, Qianwen Guo

Fare capping, where riders are not charged more than a specified maximum over a day, week, or month regardless of the number of trips, has been successfully adopted by several major transit agencies. Empirical evidence from agencies such as Miami-Dade Transit indicates that fare capping can help attract additional ridership. However, theoretical understanding of its broader impacts remains limited. Specifically, there is a lack of microeconomic models that capture how fare capping influences both ridership behavior and agency revenue. To address this gap, this paper focuses on distance-based fare capping, where fares increase with distance traveled but are subject to a maximum cumulative limit. An optimization model is proposed to design fare capping policies that maximize social welfare. The model assumes that transit agencies set fare structures while riders respond with elastic demand to fare changes. Optimal fare capping policies are derived, and their effects on ridership, revenue, and social welfare are analyzed. Numerical experiments using data from Miami-Dade Transit offer practical insights for agencies seeking to implement equitable and effective fare capping strategies.

7 - Rebalancing Modular Transit Systems: Graph-Based Optimization for Fleet Size Planning and Routing

Tina Radvand, University of Illinois at Urbana-Champaign, Urbana, IL, United States, Alireza Talebpour, Yanfeng Ouyang

Modular bus systems aim to address the scalability and flexibility challenges of current transit systems. Rebalancing the distribution of empty pods in modular bus systems is crucial for minimizing operational costs and improving system efficiency. This study aims to offer a solution to the rebalancing problem by reducing this problem to a minimum path cover and minimum cost circulation problems. The minimum fleet size and optimal pod routings are determined in the proposed approach. The unique structure of modular bus systems allows these optimization problems to be solved efficiently in polynomial time.

1 - Contextual Online Pricing with (Biased) Offline Data

Yixuan Zhang, University of Wisconsin-Madison, Madison, WI, United States, Ruihao Zhu, Qiaomin Xie

We study contextual online pricing with biased offline data. For the scalar price elasticity case, we identify the instance-dependent quantity Δ^2 that measures how far the offline data lies from the (unknown) online optimum. We show that the time length T , bias bound V , size N and dispersion $\lambda_{\min}(\hat{\Sigma})$ of the offline data, and Δ^2 jointly determine the statistical complexity. An Optimism-in-the-Face-of-Uncertainty (OFU) policy achieves a minimax-optimal, instance-dependent regret bound $\tilde{O}(\sqrt{T} \wedge (V^2T + \frac{dT}{\lambda_{\min}(\hat{\Sigma})}) + (N \wedge T) \Delta^2)$. For general price elasticity, we establish a worst-case, minimax-optimal rate $\tilde{O}(\sqrt{T} \wedge (V^2T + \frac{dT}{\lambda_{\min}(\hat{\Sigma})}))$ and provide a generalized OFU algorithm that attains it. When the bias bound V is unknown, we design a robust variant that always guarantees sub-linear regret and strictly improves on purely online methods whenever the exact bias is small. These results deliver the first tight regret guarantees for contextual pricing in the presence of biased offline data. Our techniques also transfer verbatim to stochastic linear bandits with biased offline data, yielding analogous bounds.

2 - Sample Complexity of Offline Distributionally Robust Linear Markov Decision Processes

He Wang, Carnegie Mellon University, Pittsburgh, PA, United States, Yuejie Chi

In offline reinforcement learning (RL), the absence of active exploration necessitates robust modeling to address the sim-to-real gap, where discrepancies between the simulated and deployed environments can significantly degrade the performance of the learned policy. To equip the policy with robustness in a sample-efficient manner—especially in high-dimensional state-action spaces—this paper investigates the sample complexity of distributionally robust linear Markov decision processes (MDPs), using offline data and an uncertainty set defined by total variation distance. We develop a pessimistic model-based algorithm and establish its sample complexity bound under minimal data coverage assumptions, improving upon prior work by at least a factor of $O(d)$, where d is the feature dimension. We further enhance the performance guarantee of the proposed algorithm by incorporating a carefully designed variance estimator.

3 - Pilaf: Optimal Human Preference Sampling for Reward Modeling

Yaqi Duan, New York University, Stern School of Business, New York, NY, United States

As large language models increasingly drive real-world applications, aligning them with human values becomes paramount. Reinforcement Learning from Human Feedback (RLHF) has emerged as a key technique, translating preference data into reward models when oracle human values remain inaccessible. In practice, RLHF mostly relies on approximate reward models, which may not consistently guide the policy toward maximizing the underlying human values. We propose Policy-Interpolated Learning for Aligned Feedback (PILAF), a novel response sampling strategy for preference labeling that explicitly aligns preference learning with maximizing the underlying oracle reward. PILAF is theoretically grounded, demonstrating optimality from both an optimization and a statistical perspective. The method is straightforward to implement and demonstrates strong performance in iterative and online RLHF settings where feedback curation is critical.

4 - Online Learning in Risk Sensitive Constrained Mdp

Mehrdad Moharrami, University of Iowa, Iowa City, IA, United States, Arnob Ghosh

We consider a setting in which the agent aims to maximize the expected cumulative reward, subject to a constraint that the entropic risk of the total utility exceeds a given threshold. Unlike the risk-neutral case, standard primal-dual approaches fail to directly yield regret and violation bounds, as value iteration with respect to a combined state-action value function is not applicable in the risk-sensitive setting. To address this, we adopt the Optimized Certainty Equivalent (OCE) representation of the entropic risk measure and reformulate the problem by augmenting the state space with a continuous budget variable. We then propose a primal-dual algorithm tailored to this augmented formulation. In contrast to the standard approach for risk-neutral CMDPs, our method incorporates a truncated dual update to account for the possible absence of strong duality. We show that the proposed algorithm achieves regret of $\tilde{O}(V_{g,\max} \cdot K^{\frac{3}{4}} + \sqrt{(H^4 \cdot S^2 \cdot A \cdot \log(1/\delta)) \cdot K^{\frac{3}{4}}})$ and constraint violation of $\tilde{O}(V_{g,\max} \cdot \sqrt{(H^4 \cdot S^2 \cdot A \cdot \log(1/\delta)) \cdot K^{\frac{3}{4}}})$ with probability at least $1 - \delta$, where S and A denote the cardinalities of the state and action spaces, respectively, H is the episode length, K is the number of episodes, $\alpha < 0$ is the risk-aversion parameter, and $V_{g,\max} = (1/\alpha)(\exp(\alpha H) - 1)$. To the best of our knowledge, this is the first result establishing sublinear regret and violation bounds for the risk-sensitive CMDP problem.

Data-Driven Decision Making for Social Impact

Invited Session

Applied Probability Society

Chair: Stefan Wager, Stanford GSB, Stanford, CA, United States

1 - Lfms for Education

Hamsa Bastani, Wharton School, Philadelphia, PA, United States, Tsai-Hsuan (Angel) Chung, Osbert Bastani

We will discuss recent results from large-scale randomized controlled trials leveraging large language models for education. We show how we can improve students' long-term learning outcomes by incorporating guardrails and intentional optimization of system prompts and capabilities.

2 - The Cost of Ending Extreme Poverty

Roshni Sahoo, Stanford University, Stanford, CA, United States

What would it cost to end extreme poverty? To obtain realistic and actionable cost estimates, we study poverty targeting as a statistical learning problem. In contrast to existing estimates of the global poverty gap, which assume that policymakers can perfectly target the minimum transfer required to lift each household above the poverty line, our estimates assume that policymakers have imperfect information and imperfect ability to target. In a sample of 13 countries that collectively account for 35% of the world's poor, the cost of reducing the population-weighted poverty gap index to 1% via a cash-transfer policy that targets based on observable characteristics is \$67.6B nominal per year. This cost is 2.78 times that of an oracle policy that perfectly targets the minimum transfer required to lift households above the poverty line but is 28% of the cost of universal basic income at the level of the poverty line.

3 - Markovian Search with Ex-Ante Constraints: Theory and Applications in Socially-Aware Algorithmic Hiring

Rad Niazadeh, Chicago Booth School of Business, Chicago, IL, United States

Re-designing and calibrating decision-making processes to achieve goals of equity and access in high-stakes applications, such as hiring, is one of the pillars of algorithmic fairness. Most of the literature focuses on machine learning problems in these contexts, and less attention has been given to calibrating operational decisions with operational intricacies, e.g., sequential search and selection decisions in the presences of resource limitations.

In this talk, motivated by socially-aware applications in algorithmic hiring (e.g., making the search processes fair and diverse), I will elaborate on an algorithmic framework to incorporate ex-ante constraints into "stateful" sequential search problems. Our framework includes the classic Weitzman's Pandora's box problem [Weitzman, 1978] and its extensions to joint Markovian scheduling [Dumitriu et al., 2003; Gittins, 1979], which handle richer search processes (e.g., multistage search with rejection). We show how the optimal policy in the presence of a single ex-ante constraint (such as demographic parity) retains an index-based structure similar to the unconstrained case, but may randomized between two dual-based adjustments that are both easy to compute and economically interpretable. We then extend our results to handle multiple affine constraints by reducing the problem to a variant of the exact Carathéodory problem and providing a novel polynomial-time algorithm to generate an optimal randomized dual-adjusted index-based policy that satisfies all constraints simultaneously. Next, by imposing general affine and convex ex-ante constraints, we develop a primal-dual algorithm that randomizes over a polynomial number of dual-based adjustments to the unconstrained indices, yielding a near-feasible, near-optimal policy.

4 - Value-Based Learning with Misspecified Reward Models

Peter Frazier, Cornell University, Ithaca, NY, United States, Samuel Tan

In offline contextual bandits, value-based learning trains a reward model as a function of context and executes the greedy policy with respect to the predicted reward. We study the loss function used to train the reward model and its impact on regret. Mean squared error (MSE), the typical choice, optimizes for predictive accuracy and not regret. Does this matter? A recent paper, Hu et al. 2024, seems to suggest that the answer is no, showing that the regret of value-based learning converges to the best regret achievable in the induced policy class, even when the reward model class is misspecified. But we argue that the answer is yes. By violating a critical assumption in Hu et al. 2024, we give an example of a misspecified reward model class in which the regret of value-based learning trained with MSE fails to converge to that of the best model in the reward model class. To address this limitation of MSE, we present a novel loss function, Empirical Soft Regret (ESR), for value-based learning that specifically targets regret rather than accuracy. When actions are binary, we prove that ESR asymptotically matches the best-in-class regret even when the reward model is misspecified. ESR is differentiable, supporting flexible machine learning model classes dependent on gradient-based training. In experiments on real-world decision-making problems from news recommendation and personalized healthcare, ESR significantly outperforms state-of-the-art algorithms from contextual bandits and conditional average treatment effect estimation.

5 - When Survival Meets Causal: A Framework for Decision Making on Time-to-Event Outcomes

Jessy Xinyi Han, Massachusetts Institute of Technology, Cambridge, MA, United States

Understanding not just *whether* an event occurs but *when* it happens—and how its occurrence hazard evolves over time—is central to many fields, from patient survival in healthcare and equipment failure in engineering to criminal recidivism in justice systems and customer churn in insurance. Classical survival analysis provides valuable tools for this task but often conflates association with causation and suffers from confounding bias in observational settings where treatment assignment is non-random. As a result, it cannot reliably predict outcomes under alternative interventions or policies, limiting its utility for informed decision-making.

This talk first introduces our methodological contribution, Synthetic Survival Control (SSC), a novel tensor-based approach for causal survival analysis that estimates counterfactual hazard trajectories by synthesizing weighted survival paths from comparable units. SSC enables identification in complex, real-world panel data with heterogeneous treatments and confounding, with finite-sample guarantees.

Next, I demonstrate the application of SSC and causal survival analysis through two empirical examples. In healthcare, analysis of T-cell blood cancer patient data with staggered therapy rollouts reveals clear survival improvements from new treatments. In criminal justice, we show that racial disparities in recidivism are not fully explained by risk assessment tools alone—broader contextual factors, including socioeconomic ones like unequal access to support systems, also play a critical role, underscoring important avenues for policy intervention.

By bridging survival analysis and causal inference, this framework offers interpretable, data-driven insights with broad policy implications for improving outcomes across healthcare, justice, and policy.

GPU Acceleration of Optimization Algorithms I

Invited Session

Computing Society

Chair: Matthew Galati, Amazon, Glen Mills, PA, United States

1 - Opportunities and Challenges for Lp and Mip on the Gpu**Robert Luce, Gurobi Optimization, Beaverton, OR, United States**

Recent GPU hardware generations offer high compute throughput for many applications in machine learning, scientific computing, and beyond. How does this new compute power translate into improvements in solving real-world linear and mixed-integer optimization problems in practice?

We review Gurobi's efforts and research findings on solving optimization problems on the GPU. We touch interior point methods, first-order methods, and relaxation-based MIP heuristics, and we frame these in terms of their applicability and usability on the GPU. Finally, we'll showcase how Gurobi's preliminary GPU-based components compare, performance-wise, to our standard CPU-based counterparts across a wide range of real-world models

2 - Gpu Acceleration in the Cardinal Optimizer**Nils-Christian Kempke, COPT GmbH, Berlin, Germany**

The Cardinal Optimizer (COPT) is a high-performance solver designed for large-scale optimization problems, with support for linear programming (LP), mixed-integer programming (MIP), and conic programming. In this talk, we present recent advancements in COPT's GPU-accelerated capabilities, discuss key computational and theoretical enhancements, and share performance benchmarks from the latest release.

3 - Pdlp: a Practical First-Order Method for Large-Scale Linear Programming**Miles Lubin, Hudson River Trading, New York, NY, United States, David Applegate, Mateo Diaz, Oliver Hinder, Haihao Lu, Brendan O'Donoghue, Warren Schudy**

We present PDLP, a practical first-order method for linear programming (LP) designed to solve large-scale LP problems. PDLP is based on the primal-dual hybrid gradient (PDHG) method applied to the minimax formulation of LP. The talk focuses on our more recent contributions since the 2021 NeurIPS paper, namely: the C++ implementation in Google's OR-Tools, the feasibility polishing heuristic, and a new collection of large-scale test instances.

4 - Parallel by Design : Gpu-Powered Optimization at Nvidia**Chris Maes, Nvidia, San Francisco, CA, United States**

This talk gives an overview of cuOpt, NVIDIA's GPU-accelerated solver for linear (LP) and mixed-integer (MIP) programs. We focus on two GPU-native LP solvers: a parallel implementation of Mehrotra's predictor–corrector method and PDLP, a recent first-order method based on the primal–dual hybrid gradient algorithm. We also highlight advances in GPU-based heuristics for MIP and discuss how GPU and CPU algorithms can be combined to solve a wide range of optimization problems.

5 - GPU-Accelerated Optimization Approaches with FICO(R) Xpress**Dinakar Gade, FICO, Bozeman, MT, United States, Michael Perregaard**

This talk will present observations on the integration of GPU-acceleration techniques using FICO(R) Xpress Solver. We will present early-stage insights into the use of GPU-based algorithms with a focus on the primal-dual hybrid-gradient algorithms for LP solving and areas where GPUs acceleration can be exploited. We will present considerations for hardware and software development and discuss future avenues to improve upon these methods.

Co-Chair: Hao Hu, Clemson University, Clemson, SC, United States

1 - Facial Reduction in Biqcrunch**Ian Sugrue, Morehead State University , Morehead, KY, United States**

BiqCrunch is a binary quadratic solver that uses a semidefinite bounding procedure with a branch-and-bound framework to get exact solutions to combinatorial optimization problems. Since its latest official update, BiqCrunch has undergone further development, most notably the inclusion of the dimensionality reduction process known as facial reduction. We will discuss the details of how facial reduction is implemented, the numerical results that support this inclusion, as well as future development plans for BiqCrunch.

2 - Facial Reduction for Semidefinite Relaxations of Combinatorial Optimization Problems**Hao Hu, Clemson University, Clemson, SC, United States, Mingming Xu, Boshi Yang**

In this talk, we present new findings on facial reduction for semidefinite relaxations of combinatorial optimization problems. In semidefinite programming (SDP), Slater's condition is crucial for both theoretical convergence guarantees and the practical performance of optimization algorithms. When Slater's condition fails, facial reduction can restore it through a finite sequence of reformulations. However, these reformulations often involve solving auxiliary optimization problems that can be as challenging as the original. Recent research has therefore focused on developing more efficient strategies for performing facial reduction.

In our work, we specifically consider SDP problems that arise as relaxations of combinatorial optimization problems. This perspective enables us to exploit the underlying combinatorial structure, allowing the development of novel and highly efficient facial reduction techniques. We establish theoretical results demonstrating the effectiveness of our approach. Numerical experiments further show that applying our specialized facial reduction method significantly improves both the speed and accuracy of solving SDP problems.

3 - SDP Approach to Quadratic K-Vertex-Disjoint Paths Problem**Mingming Xu, Clemson University, Clemson, SC, United States, Hao Hu**

We consider the quadratic k -vertex–disjoint paths problem (Q-VDP). Given a directed graph G and k source–target pairs $(s_1, t_1) \dots (s_k, t_k)$, the objective is to find k mutually vertex–disjoint paths that minimize a quadratic cost function. Such quadratic objectives naturally arise when interactions among paths matter. The problem is NP-hard when k is part of the input. In this work, we formulate Q-VDP as an integer quadratic program and derive semidefinite-programming (SDP) relaxations. We also develop a

tailored Alternating Direction Method of Multipliers (ADMM) to solve these relaxations, yielding a fast algorithm that recovers exact solutions in practice. Numerical results show that our method finds optimal solutions faster than the commercial solver Gurobi.

4 - Cuhallar: a Gpu Accelerated Low-Rank Augmented Lagrangian Method for Large-Scale Semidefinite Programming

Arnesh Sujarani, University of Waterloo, Waterloo, ON, Canada, Renato Monteiro

This talk discusses cuHALLaR, a GPU-accelerated implementation of a solver for solving large-scale semidefinite programming (SDP) problems. We demonstrate how our Julia-based implementation efficiently uses GPU parallelism through optimization of simple, but key, operations, including linear maps, adjoints, and gradient evaluations. Extensive numerical experiments across three problem classes—maximum stable set, matrix completion, and phase retrieval show significant performance improvements over both CPU implementations and existing GPU-based solvers. For the largest instances, cuHALLaR achieves speedups of 30-140x on matrix completion problems, up to 135x on maximum stable set problems for Hamming graphs with 8.4 million vertices, and 15-47x on phase retrieval problems with dimensions up to 3.2 million. cuHALLaR efficiently handles massive problems with matrix variable of dimension up to 8 million and number of constraints up to 300 million at 10^{-5} relative precision. It matrix completion instances with over 8 million rows and columns in just 142 seconds. These results establish cuHALLaR as a very promising GPU-based method for solving large-scale SDPs.

5 - Convexification of Bilinearly Constrained Set

Hyun-Ju Oh, Clemson University, Clemson, SC, United States, Margaret Wiecek, Boshi Yang

In this talk, we present the convexification of sets defined by box constraints and bilinear inequalities, in which all bilinear monomials share a common variable. We show the polyhedrality of the convex hull of such sets and present its linear and vertex descriptions.

1 - Enre Student Best Paper Award: Adaptive Robust Optimization with Data-Driven Uncertainty for Enhancing Distribution System Resilience

Shuyi Chen, Carnegie Mellon University, Pittsburgh, PA, United States

Extreme weather events are placing growing strain on electric power systems, exposing the limitations of purely reactive responses and prompting the need for proactive resilience planning. However, existing approaches often rely on simplified uncertainty models and decouple proactive and reactive decisions, overlooking their critical interdependence. This paper proposes a novel tri-level optimization framework that integrates proactive infrastructure investment, adversarial modeling of spatio-temporal disruptions, and adaptive reactive response. We construct high-probability, distribution-free uncertainty sets using conformal prediction to capture complex and data-scarce outage patterns. To solve the resulting nested decision problem, we derive a bi-level reformulation via strong duality and develop a scalable Benders decomposition algorithm. Experiments on both real and synthetic data demonstrate that our approach consistently outperforms conventional robust and two-stage methods, achieving lower worst-case losses and more efficient resource allocation, especially under tight operational constraints and large-scale uncertainty.

2 - Enre Early Career Best Paper Award: Regression Equilibrium in Electricity Markets

Vladimir Dvorkin, University of Michigan, Ann Arbor, MI, United States

In two-stage electricity markets, renewable power producers enter the day-ahead market with a forecast of future power generation and then reconcile any forecast deviation in the real-time market at a penalty. The choice of the forecast model is thus an important strategy decision for renewable power producers as it affects financial performance. In electricity markets with large shares of renewable generation, the choice of the forecast model impacts not only individual performance but also outcomes for other producers. In this paper, we argue for the existence of a competitive regression equilibrium in two-stage electricity markets in terms of the parameters of private forecast models informing the participation strategies of renewable power producers. In our model, renewables optimize the forecast against the day-ahead and real-time prices, thereby maximizing the average profits across the day-ahead and real-time markets. By doing so, they also implicitly enhance the temporal cost coordination of day-ahead and real-time markets. We base the equilibrium analysis on the theory of variational inequalities, providing results on the existence and uniqueness of regression equilibrium in energy-only markets. We also devise two methods to compute regression equilibrium: centralized optimization and a decentralized ADMM-based algorithm.

3 - Enre Best Publication Award - Energy: Scaling up Electric-Vehicle Battery Swapping Services in Cities: a Joint Location and Repairable-Inventory Model

Wei Qi, Tsinghua University, Beijing, China, People's Republic of

Battery swapping for electric vehicles is reviving but faces a tension between maximizing battery proximity to users and grid constraints on decentralized charging. Cities are adopting infrastructure where decentralized swapping stations replenish charged batteries from centralized charging stations. This paper models this network (handling non-Poisson swaps and stochastic operations) and proposes a joint location-inventory model with a nonconvex objective, solved exactly via constraint generation and parameter search algorithms (speeding up by three orders of magnitude over Gurobi). The key insight is that it is the faster charging at centralized stations, not just pooled demand, that justifies the “swap-locally, charge-centrally” network by reducing system-wide battery stocks. In a broader sense, this work deepens our understanding of how mobility and energy are coupled toward enabling smart cities.

4 - Enre Best Publication Award - Natural Resources: from Curtailed Renewable Energy to Green Hydrogen: Infrastructure Planning for Hydrogen Fuel-Cell Vehicles

Long He, George Washington University, Washington, DC, United States

Hydrogen fuel-cell vehicles (HFVs) are a promising solution for sustainable transportation, particularly in regions with excess renewable energy. They can simultaneously reduce energy curtailment and promote green transport. This paper addresses key challenges to HFV adoption—uncertain demand, lack of infrastructure, and a spatial mismatch between hydrogen production and consumption. We develop a planning model to determine optimal locations and capacities for refueling stations and production plants, along with necessary grid upgrades. Applying our model to China's Sichuan province, we find that the optimal infrastructure layout depends on the adoption target. Higher targets shift deployment to major transportation hubs. We also show that promoting HFVs helps reduce hydropower curtailment and that hydrogen's transport flexibility allows for greater cost savings and curtailment reduction than other alternative fuel vehicles, e.g., electric vehicles.

5 - Enre Best Publication Award - Environment and Sustainability: Flattening Energy-Consumption Curves by Monthly Constrained Direct Load Control Contracts

Ali Fattahi, Johns Hopkins University, Baltimore, MD, United States

Balancing electricity demand and supply is one of the most critical tasks that utility firms perform to maintain grid stability and reduce system cost. Demand-response programs are among the strategies that utilities use to reduce electricity consumption during peak hours and flatten the energy-consumption curve. Direct load control contracts (DLCCs) are a class of incentive-based demand-response programs that allow utilities to assign “calls” to customer groups to reduce their energy usage by a

prespecified amount for a given length of time. Given the rapid expansion of such contracts, we develop an integer stochastic dynamic optimization problem for executing DLCCs that minimizes total system cost subject to monthly and annual constraints on the number of times and hours customers can be called. We develop a hierarchical approximation approach, which consists of an annual problem and monthly problems. Motivated by the practice in a large utility firm in California, we incorporate a reduce-to-threshold policy that attempts to flatten energy-consumption curves whenever demand exceeds a given threshold. We verified the quality of our proposed approach on real data from the California Independent System Operator, which is the umbrella organization of the utility firms in California, and measured the quality of our solution against a lower bound. A large utility firm in California implemented our model and informed us that the additional reduction in cost was approximately 4%. Our sensitivity analysis reports the impact of managerial concerns on some policies to enhance customer experience and provides insights for improving the features of DLCC contracts.

ENRE: Electricity

Chair: Bolun Xu, Columbia University, New York, NY, United States

Co-Chair: Liudong Chen, Columbia University, New York, United States

1 - Market Options for Improving Fairness and Reliability of Wind Farm Grid Integration

Robert Mieth, Rutgers University, Piscataway, NJ, United States

Off-shore wind power is projected to become a major supplier of electric energy in the near future due to the maturity of the technology, its decreasing cost, larger turbine sizes, and the advantage of accessing higher and more consistent wind speeds at sea compared to onshore wind. At the same time, off-shore wind turbines are harder to maintain because of uncertain metocean conditions and limited maintenance vessels. This makes ensuring the reliability of off-shore wind farms a risk both for the wind farm and the grid operator because derating a wind farm for maintenance under uncertain wind speeds and maintenance access with non-trivial planning constraints can significantly impact profits and energy supply. This risk has largely been overlooked by existing research which has mostly focused on risk from uncertain wind production. This talk discusses the modeling and analysis of maintenance planning for off-shore wind in a competitive electricity market. First, we discuss the impact of wind farm maintenance on electricity prices and farm profits and present both strategic and grid-serving maintenance planning tools. Building on these results we discuss fair and welfare-maximizing options for market-based and data-driven coordination between the grid and off-shore wind farms with maintenance constraints.

2 - Fair-over-Time Distributed Energy Resource Coordination

Johanna Mathieu, University of Michigan, Ann Arbor, MI, United States, Hannah Moring, Xavier Farrell
